14480

ENGINEERING NEWS

VOLUME IV.

FROM JANUARY TO DECEMBER,

1877.

GEO. H. FROST, PUBLISHER,

CHICAGO.

TABLE OF CONTENTS.

A

Accident, the New York Post Office.... 125
—— to a Caisson, etc..... 152
Albany, Specifications and Bids for Western Ave. Improvement.... 63
American and Foreign Railways, Observation on..... 43
—— Engineering, Rise and Progress of (See Errata).....17, 21
—— Institute of Architects, Chicago Chapter of.....24 87
—— Iron and Steel..... 183
—— Railways, The Interest, Value and Future Prospects of.... 320
—— Scientific and Technical Journals 69
—— Society of Civil Engineers...20 46, 89, 106, 117, 126, 191, 139, 234, 253, 260, 292, 296
American Society of Civil Engineers, Constitution of..... 320
By Laws of..... 330
Application of Photography to Trigonometric Surveys 130
Arch, Account of an Experiment on a Concrete 57
Arches, Considered Graphically..... 16 22, 30, 42, 50, 66, 82, 100, 108 116, 124, 140, 160, 170, 178, 193 201, 214, 284, 291, 317, 358,
Architecture, Town, and Modern Problems 173
Are Resident Engineers Necessary?.... 117
Arthur, Col., on Railway Management. 301
Artistic Engineering..... 134
Ashtabula Bridge, The.....19, 23
—— Committee Report of Ohio Assembly on..... 133
—— Details of..... 46
—— On the Failure of..215, 225, 231, 240
—— Calamity, The..... 32
—— Disaster, The.....7, 11, 61
—— The Testimony on..... 35

B

Baltimore, The Permanent Water Supply of 128
Bangor, Me., Description of Water Wks., 59
Barnacles, Fast Freight..... 227
Bergen Tunnel, The..... 157
Bessemer Steel Works..... 299
Bill to Provide a State Board of Health, A 61
Blasting of Ice in Winter of 1875, Memoranda respecting..... 12
Boiler Feeder, Improved..... 113
Bonnet Carre Crevasse, Trip of Civil Engineers to..... 114
Book Notices.
Formulæ for R. R., Earthwork.. 27
Iron Highway Bridges..... 48
Text Book on Mineralogy..... 73
The Forces of Nature..... 146
Strength and Determination of the Dimensions of Structures of Iron and Steel..... 154
Strength and Calculation of Dimensions of Iron and Steel Constructions..... 154
Graphical Analysis of Roof Trusses for the Use of Engineers, Architects and Builders..... 159
New Constructions in Graphical Statics 244
A Treatise on the Use of Belting for Transmission of Power.... 244
A Treatise on Engineering Construction 244
The Pocket Geologist and Book of Minerals 253
Theory of Transverse Strength and its Application in Construction of Buildings..... 253
Water Supply Engineering..... 259
An Elementary Course of Civil Engineering 260
Elements of the Method of Least Squares 308
Elements of Descriptive Geometry, Shadow, and Perspective.. 301
Border, The New York..... 129
Boston, Improved Sewerage for..... 187
—— Society of Civil Engineers.... 75
Bricks, Stone, and Cement, Experiments with 97
Bridge Accidents, Railroad..... 31
—— Building, Skill and Conscience in 32
—— Cincinnati Southern Railroad.. 328 (See Correspondence 332)
—— Erection of Verrugas..... 25
—— Fairmount, Illustration of.... 132
—— Girard Avenue " " ... 54
—— Highway, " " ... 48
—— Iron Highway, " " ... 156
—— Over Missouri River at St. Joseph, Illustration of..... 80
—— The Kentucky River..... 37
—— The Point..... 89
—— The Sterling..... 283 (See Ashtabula Bridge.)
—— Trusses 75
—— —— (See Correspondence 9, 47, 99.)
Bridging, Prairie Creek..... 20
Bridges, A Bill to Secure Greater Safety for Public Travel over..... 136
—— Iron 40
—— —— (See Wrought Iron Girder Work)
—— (See Correspondence and General Intelligence)
Brookfield Tunnel, The..... 95
Brotherhood of Locomotive Engineers, The.....72, 76
Boundary Survey, The..... 316
Buildings, Strength of..... 139
Bursting of Staffordville Dam..... 75
Business Outlook, The..... 247
—— Prospectus for 1877..... 71

C

Caisson at Willem Bridge, at Rotterdam, Accident to..... ... 152
Calumet Marshes, Artificial Drainage of 41
Canadian Trunk Lines..... 327
Canal, The Erie..... 165
—— The Nicaragua..... 8
Canals, The New York..... 11
Candle, The Electric..... 255
Cars, Hotel..... 198
—— Palace..... 353
Cement, Portland..... 168
Cements and Concretes,.....51, 58, 61 68
Chicago after the Great Fire, City Surveying in..... 311
—— Chapter of American Institute of Architects.....24, 87
—— Court House..... 312
—— —— —— Measurement of Work in 343
—— First Annual Report of Department of Public Works..... 335
—— Pumping Engines 172
—— —— —— The West Side..... 70
—— The Steel Rail Industry in..... 14
—— The Wooden Pavements of..... 287
—— Water Works, Lake Crib of.... 224
—— Gas, West..... 172
—— (See Specification for Machinery, etc.)
Cincinnati Southern Railroad Bridge ... 328
Circle Dividing Instruments..... 93
Cistern, A New Fire..... 184
City Surveying. (See Correspondence 20, 332)
Civil Engineer. Sanitary Reform and the 263
—— Engineering, Wanted; a Text Book on..... 75
—— Engineers, American Society of (See American Society of Civil Engineers.)
—— Engineers, Boston Society of.... 75
—— —— Club of the Northwest..9, 38, 59 75, 83, 101, 157, 161, 240, 279, 304 311, 352
—— —— Club of St. Louis.....38, 354
Cleveland 319
Coal Gas..... .....10. 13
—— —— Dangers From..... 347
Cold, On the Mechanical Production of 119
Columns, Strength of..... 93 (See Errata and Correspondence, 92, 163)
Commercial Panics, Responsibility for.. 290
Competition, Railroad..... 157
Concrete Arch, Account of an Experiment on..... 57
Condensation of Steam (See Cylinders of Steam Engines, etc.)
Conditions of Safety in Public Buildings 19
Conduit, (See Specification for Machinery, etc).
Consolidating Earth that has Slipped, Report on Method of..... 257 266. 271, 279
Construction and Working of St. Gothard Railway..... 129
—— On Tunnel.....281, 288, 297
Contractor's Intelligence..64, 107, 132, 168, 192 (See General Intelligence.)
Co-ordinate Surveying.....101, 111, 121

Correspondence:

Bridge Designing..... 9
Toronto Miscellany..... 13
Locating Quarter Section Posts on North Side of Section.—Kirkwood's Formulæ for Discharge of Sewers.—Witch Hazel.—Hydraulic Formulæ.—Surveyor's Use of Transits, etc..... 14
Gleanings 15
City Surveying.—Hydraulic Problem..... 20
Correction for Hydraulic Formula, p. 14.—Witch Hazel.—Use of Engineering News to Students.—Economy of Heat in Steam Engines. — Answer to Hydraulic Problem p. 20.—Independence in Surveys.—Improvement of the Lower or Des Moines Rapids of the Mississippi River..... 27
Rise and Progress of American Engineering.—Toronto News. —Method of Keeping Level Notes.—Land Slides on the Lower Mississippi.—Gurley's Cheap Instruments..... 33
Answer to Hydraulic Problem 20, 38
Skill and Conscience in Bridge Building.—New York News.—Comparison of Iron and Combination Bridges as to their Respective Merits 47
Correction of Editoral Note, p. 36. —Keeping Level Notes.—Kirkwood Formula for Discharge of Water through Pipes and Sewers Discussed, 53.—Answer to Economy of Heat in Steam Engines, p. 27.—Rules for Measuring Plastering, etc.—County Surveyors.—Question for Surveyors and Reply. — Trautwine's Pocket Book, etc.—New York News..... 57
Principle of Eads' Jetty System.. 58
Response to Answer to Economy of Heat in Steam Engine, p. 57.—Kirkwood's Formula further Discussed. — Chalk Beds in Kansas, etc.—Conversazione of Mining Engineers. — The American System of Keeping Level Notes..... 62
Keeping Level Notes..... 68
Keeping Level Notes.—Lumber Famine.—Ownership of Beaches. — Kirkwood's Formula. — Graphical Analysis of Roof Trusses, by Prof. C. E. Greene. —Comparative Cost of Coal and Oil Gas..... 73
Keeping Level Notes. —Reduction of Level Notes.—Keeping Level Notes.—Merits and Defects of Different Bridge Systems..... 79
Binding Periodicals.— Economy of Heat in Steam Engines.... 80
Galveston News.— Jacksonville, Fla., Water Works.—Words of Praise.—Massachusetts News — Engineering News for Road Commissioners.—Observations upon Sewers and Formulæ.—County Surveyors *versus* Law 91
Notes on the Formulæ for Strength of Columns..... 92
Question Concerning Velocity and Capacity of Sewers.—Strains in Bridge Truss..... 99
Wisconsin News. — Hydraulic Formulæ and Answer to Question Concerning Velocity and Discharge of Sewers.....09, 114
Brick Street Gutters.—Establishing Quarter Section Corner. —Surveying Note..... 123
Tar and Gravel Concrete Street Gutters.—Drainage of New Orleans. — Re-establishing Lost Quarter Section Corner..... 130
Establishing Lost Section Corner. —Answer to Drainage of New Orleans, p. 130..... 146
Problem Proportioning Railway Culverts.—Jetty News.—Kansas City Water Works Reply. Correction for Dubois' Graphical Statics..... 153
Force of Falling Bodies.—Proportioning R'y Culvert Answer. 158
Question Respecting Re-establishing a Section in Interior of a Township with Corners Lost.—Nautrigon.—Formula for Cross Section of Truss Member Having Tensile and Compressive Strains..... 163
Railway Culvert Problem, Response 167
Errata for Correction for Dubois' Graphical Statics.—Queries respecting Formulæ for Horse Power of Engines..... 174
Railroad Culvert Problem, Rejoinder. — Recording Plats.—Telemeter Surveying..... 183
The Nautrigon.—Steel Tapes under Strain.—Railway Culvert Problem, Solution of.—Recording Plats, Answered.—A Log Survey 191
Alton Water Works..... 198
Latham's Sanitary Engineering Corrections 234
Propelling Canal Lock Gates... 244
Cincinnati Southern R. R. Bridge, Correction..... 259
Determining the Direction and Velocity of River Currents.—Municipal and Individual Rights as affecting the Natural Drainage of a City..... 301
Municipal and Individual Rights as affecting the Natural Drainage of a City, Answers 315 316
Standard Rods in Cincinnati —Test of Cincinnati Southern R. R. Bridge..... 332
Hydraulic problem..... 340
Query respecting the Cincinnati Standard as Compared with the Chesterfield Standard. — Can a City compel the Use of a Meter differing from the U. S. legalized Standard? Iowa Notes..... 354
County Highways..... 101
Court House, The Fall of the Winnebago County..... 125
Creek Bridging, Prairie..... 20
Croton Water Works and supply for the future, Notes on..... 28
Curves, Elevation of Outer Rail on..... 149

Culverts, Proportioning (See Correspondence, 191)
Cylinders of Steam Engines, Hypothesis of Condensation and Re-evaporation of Steam in the, 158

D

Dam, Loss of the Staffordville.....75, 83
Damp Houses..... 182
Dams, Movable..... 141
Danger from Coal Gas..... 347
Danube, On the Mouths of, etc.,..... 137, 141, 149
Decision of U. S. Supreme Court Important..... 72
Defective Sewerage..... 85
Departmental Reports, The President's Message and..... 343
Description of Water Works at Bangor..... 59
Detroit..... 303
—— Annual Message of Mayor of... 24
—— and Milwaukee R. R. Improvement..... 247
—— New Water Works of..... 179
—— Tunnel, The..... 55
—— Tunnel, "Proposed..... 35
Dimensions, Determination of..... 60
Direction and Speed of River Currents Method of Determining..... 284
Dominion, Land Surveying in the 171, 187 204, 207, 224, 248, 255, 263
Drainage, Discussion on House..... 78
—— Municipal and Individual Rights as affecting (See Correspondence 35, 316)
—— Montreal Main..... 133
—— of Calumet Marshes, Artificial 41
—— of New Orleans, Topography and,.....114, 121
—— of Zuyder Zee..... 130
Drinking Water and its Impurities..... 198
——, Bad Odors of..... 218
Dynograph, The..... 192

E

Eads' Jetties..... 295
Eagle Harbor, Lake Superior, Removal of Rock Obstructing Entrance to 65
Earth that has Slipped, Report on Method of Consolidating. 257 266, 271, 279
Economical Use of Railways, 215, 223, 231, 239, 247, 255
Economy, Puddling Furnace..... 166
——, Railway..... 195

EDITORIAL NOTES.

Consolidation of Railways with Illinois Central.—Bridge designing, Comments on..... 9
Legislative Action respecting the Inspection of Bridges.—Concerning "Specially to Land Surveyors." 11
The Governor of New York on the State Survey.—Baron Von Weber on Annoyance to Result to English Railway Managers, upon Completion of the Channel Tunnel.—Continuous Girders... 12
Working Drawings and Strain Sheets of Bridges, purchased by University of Michigan.—Detroit Tunnel Project.—Committee for Testing West Side Water Works. 19
Allowance for weight of Snow on Roof Trusses.—Pumping engine Tests.—Respecting Location of Quarter Corner on the North Line of Section.—Canal Navigation.—Miltimore Car Wheel and Axle..... 24
Removing Snow from Railroad Tracks.—Action of Common Council respecting Prevention of Waste in the Use of Water, New York. Also respecting "Contractor for Tapping Croton Water Mains."—Cost of Removing Snow in New York City.—Use of Corners of Permanent Buildings as monuments in City Surveys, in Chicago..... 31
President's Message to Congress on Board for Testing Iron and Steel.—Rapid Transit in New York.—Rope Gearing.—Excellent Sewerage in Chicago.—Poughkeepsie Bridge Company.—Bridge at Kansas City.—Cornish engines at Louisville, Ky.—Charles Collins.—Railroad construction in Ohio.—Sawing Granite.—Preservative for Timber.—Engineers' Societies.—Report of City of Middletown, Conn..... 36
Legal Decision in favor of New York Elevated R. R. Co.—"Sanitary Inspector of Schools."—Franklin Institute.—Rice's Pontoon Bridge.—American Society of Civil Engineers.—Test of West Side Pumping Engines.—Underground Railroads, New York,..... 44
New York and Harlem R. R.—William Sooy Smith..... 45
Clemens Herschel on Railroad Bridges.—Corrections respecting Ashtabula Bridge.—A Highway Bridge at Elgin.—"Cements and Concrete."—Use of Iron in frames of Railroad Cars..... 51
Claims against Cook County Court House by Egan, Architect.—New Court House.—"Blue Glass."—American Society of Civil Engineers.—Contractor's Intelligence.—American Institute of Mining Engineers,..... 59
Detroit Water Works..... 67
South Pass.—Milwaukee Ave. Viaduct.—American Society of Civil Engineers.—Considerations Influencing the Placing of Windows in Building..... 68
Water Consumption, Daily, in Boston..... 71
Civil Engineer's Club of the North West. Latham's Sanitary Engineering.—Sewerage and Sanitary Reports.—Back Numbers.—Correction for "Cement and Concretes."..... 72
Failures of Dams.—Proposed Book on Ashtabula Bridge Accident.—Sanitary Engineering.. 83
Iron Sleepers.—Bridge Truss.—Chicago Water Works Crib.—Exits of McCormick's Hall.—Burning of Southern Hotel.—Chicago Chapter of American Institute of Architects..... 87
Crib of Chicago Water Works.. 93
Transactions of American Society of Civil Engineers.—Dr. Weyrauch's Strength and Determination of the Dimensions of Structures of Iron and Steel.—Chicago Delegation to Convention of American Society of Civil Engineers at New Orleans..... 94
The proposed Detroit Tunnel.—Philadelphia and Reading R. R. Co's Notice to Locomotive Engineers.—Dr. Siemen's on Technical Schools.—Boiler for Impregnating Timbers..... 110
Courtesies to Engineers attending the late Convention at New Orleans.—Gold Medal Award for Dynograph.—Detroit Tunnel.—Personal.—Lehigh R. R. Co. *versus* Brotherhood of Locomotive Engineers.—Rockford Calamity..... 126
Stereoscopic Views of Engineering Structures.—Coroner's Jury in the Rockford Court House Disaster.—Chicago and Sanitary Matters.—Architectural Shams.. 133
Tidal waves in Lakes.—Roger's Statuary..... 141
Larger Car Wheels..... 149
Fall of a Suspension Bridge in England.—Moveable Dam on the Ohio.—The Sutro Tunnel.—Paper on Sewers and Sewer Building..... 157
Heavy Rainfalls.—"Fall of Suspension Bridge in England."—Tying Bridge Trusses to abutments..... 161
Ohio Canal..... 165
Answer to "Establishing Section in Interior of Township when Corners are lost."—New Orleans and Pacific R. R.—South Pass Progress.—New Orleans..... 171
San Antonio Water Works.—Sewer Tunnel, Montreal.—Steam Motors on Third Ave. R. R., New York City.—Conduit for Oil, New York.—New York and Brooklyn Bridge Co..... 179
Asphalt Pavements in Boston.—Mortar for the Lake Superior Smelting Works.—Cleveland Viaduct.—Proposals for Contracts.. 187
The Strikes..... 195
Sanitary Engineering.—Railroad Management and the Strikes.... 203
Ærial Torpedoes..... 204
Civil Engineers' Club of the North west.—Preserve Your Back Numbers.—Sheets for Binding.—Volume Second.—Erratum "Objects of Interest in Pittsburgh" 207
Shaking off Railroad Barnacles.. 224
"Various Methods of Consolidating Earth that has Slipped.." 255
Tile Drainage in Illinois.—Farm Drainage, a Possible Field for Engineers.—To Engineers in Search of Employment.—Growing Demand for Improved Sanitary Conditions..... 279
Flour Barrels and Rotten Wood for City Pavements..... 311
Corrections Regarding Water Works Questions.—American Society of Civil Engineers.—A Bill to Promote Industry and Labor without Increase of Public Debt. 319
American Statesmen and Public Works..... 320
Gen, Humphrey's Report—Decree against Erie Railway Co.... 321
Milwaukee Bridge & Iron Works.—East River Bridge Cables.—Michigan Ship Canal.—Gilbert Elevated Railway, New York.—A Culvert Washout.—Survey on Atlantic & Pacific R.R.—St. Louis Papers on Government Engineers.—Agitated Railway Connection between Toronto and Ottawa.—Gens. Gilmore and Duane's Report on Washington Monument.—Coney Island R. R.—Edison's Remarkable Telephone..... 327
Food for Reflection on the Tariff Question.—New Through Lines from the West to New England.—Sonora Railway.—Drainage of New Orleans.—elf Moving Terrestrial Globe..... 328
Chicago City Engineer..... 335
The Public Works of Chicago.—E. S. Chesbrough.—American Locomotive Building.—Edward M. Grant, C. E.—Steamship Line to Brazil.—Congress and the Paris Exposition.—New Orleans Pacific Railway..... 326
Grand Jury Indictments 337
A Bill for Preliminary Survey of African Railway.—Davis Island Dam.—"A Very Narrow Gauge."—Government Commission on Chicago Custom House.—The South Pass Jetties.—The Floods in Virginia.—Catchment Basins of English Rivers.—Intercolonial Railroad.—Ohio Legislature and the Canals.—Erie Canal and Others.—Quarrel between Congressional Committees.—Reservoirs to Regulate the Volume of Water in Upper Mississippi.—Estimates for National Improvements..... 345
The Slimy Wooden Pavements of Milwaukee.—The Commission on the Chicago Custom House.—Maritime Canal in France.—Improvement of the Cumberland.—The Telephone..... 351
The New Ashtabula Bridge.—Proposed Commission to Examine Plans for the Improvement of the Mississippi and its Tributaries.—Treaty with Nicaragua Referring to the Proposed Inter-Oceanic Canal.—Government Work at Wilmington Harbor, Cal.—The New Court House.—The Stonework of the Chicago Court House—The Formation of Water Boards.—The Lease, etc., of the Cincinnati Southern Railway.—The Jetty Channel and Dredge Boat—The Cost of the Jetties.—The Next Payment on the Jetties. 352
Chicago and Alton, Proposed Extension..... 367
Secretary of War on next Jetty Payment.—New Railway Journal.—Toronto & Ottawa Railway—Water Gas.—Kentucky River Improvement,—Letter of Col. Roberts on Jetties..... 368
Education by School Shops, Manual.... 55
—— Technical..... 234
Electric Candle, The..... 255
Electricity, Transmission of Power by.. 109
Elevated Railway, The New York..... 298
—— Railroads..... 331
Elevation of Outer Rail on Railroad Curves..... 149
Engineer, Sanitary Reform and the Civil 203
Engineering, Artistic..... 134
—— Projects, Influence of Seasons on 23
—— Rise and Progress of American. 17, 21
—— Society, Liverpool..264, 304, 328, 352
—— Training; Its Strong and Weak Points..... 7
Engineers, Are Resident, Necessary?.... 117
—— As Railway Superintendents.... 84
—— Brotherhood of Locomotive...72, 76
—— Locomotive..... 86
Engines, Chicago Pumping..... 172
—— Pumping..... 102
—— —— The West Side..... 70
Entrance to Galveston Harbor, Improvement of..... 236
Erection of the Verrugas Bridge, The.. 25
Erie Canal, The..... 165
Errata, Graphical Statics, DuBois (See Correspondence).....153, 174
—— Latham's "Sanitary Engineering" (See Correspondence)..... 234
—— "Metric Discussion"..... 271
—— "Our Railroads and their Economical Use"..... 234
—— "Rise and Progress of American Engineering," (see Correspondence 33
Strength of Columns..... 101
Erratum, "Objects of Interest in Pittsburgh" 207
Errors in Leveling Probable. 77, 84, 92, 98, 104
European Cities, Water Supply of..... 85
Expedition around the World, Proposed Scientific 45
—— Woodruff Scientific..... 161
Experiment on Concrete Arch, Account of..... 57
—— with Bricks, Stone and Cement. 97

F

Failure of the Ashtabula Bridge, On the.....215, 225, 231, 240
Fairmount Bridge, Illustration of 132
Fall of the Winnebago Court House... 125
Fascines in Public Works of Holland, Use of.....162, 166
Fast Freight Barnacles..... 227
Fire Cistern, A New..... 184
Floating Light Houses..... 56
Florida Notes.....131, 286, 325
Formulæ for Cross Section of Truss Members (see Correspondence,) 79. 92. 163
—— for Sewer Discharge, (See Correspondence) 14, 53, 62, 91, 99, 114
—— for Proportioning Culverts, (See Correspondence)..... 191
Fulton, Robt., Letter from, to Jas. Madison..... 337
Furnace Economy, Puddling..... 166
—— Gas, Utilization of..... 38
Future Prospects of American Railways, The Interest, Value and..... 320

G

Galveston Harbor, Improvement to Entrance of..... 236
Gas, Coal.....10, 13
—— Coal and Oil, Comparative cost of (See Correspondence)..... 73
—— Consumers should not Favor Competition in its Supply, Some of the Reasons Why..... 315
—— Danger from Coal..... 347
—— Lighting Railway Cars with, 252, 296
—— Utilization of Furnace..... 38
—— West Chicago..... 172

GENERAL INTELLIGENCE

Bridges. 199. 205, 211, 218, 227 238, 244 253, 261. 269, 277, 285 293, 302 309, 317, 332
Contractors, 200, 205, 212, 220, 228 309, 318, 325. 333, 341

ENGINEERING NEWS.

ENGINEERING TRAINING—ITS STRONG AND WEAK POINTS.

As we stated two weeks ago, we felt moved on reading the letter, an extract from which we printed in the ENGINEERING NEWS of Dec. 23, to add some words of encouragement, of advice and of caution, to our young brethren. We offer them therefore to-day, hoping that they will be received in the kind spirit in which they are intended.

It is comparatively but a few years since special schools were established in this country for the training of engineers. Before that time the desired theoretical knowledge beyond some mathematical drill, was usually acquired under the guidance and in the office of a working engineer, a busy man who had little time to oversee the study of his pupils and to lead their efforts in the right direction. As he naturally could not give the best of his energies to systematizing his instruction and improving his methods, we can easily see how better results can be accomplished with a less expenditure of time, when pupils are placed with men who make it their whole business to guide them aright. In this way the young engineer is rapidly placed in possession of the theory of his profession, all the facts are arranged so as to come in natural sequence, and the latest discoveries, improvements and results of experimental research are laid before him.

Again, if we go back to the time of the youth of engineers who are still active in their vocation, we shall find that many problems have been successfully solved since then. All investigators are striving to extend the bounds of human knowledge, and the progress in all branches of science, during the last fifty years has been simply wonderful. The time has probably passed when uneducated men, with only sound common sense and indomitable pluck, can make that mark in the engineering profession which some of the late famous engineers of England have done. Railroads were then in their infancy with all those classes of work which they called into existence. The modern theory of structures has grown up altogether since that time. Thermodynamics, the useful applications of electricity, and many powerful inventions have been developed in late years. The task is formidable to the man who should undertake, unaided, to inform himself thoroughly of the present state of knowledge, and to go forward, shoulder to shoulder, with the workers in science.

Does the young engineer ever consider how fortunate it is that the assistance of the nation or the state, or that private endowment places within his reach, the services of instructors, the collections of models and illustrations of all kinds, books on science and technology in abundance, very little, if any, of which aids he could command with the fees which he is called upon to pay. In place of being obliged to search through and read authors in great numbers for information which he thinks may be of use to him, the authorities are collated, references are made, and he is given a course of instruction which is deemed to be most judicious for his chosen vocation, at a time too when his ignorance of all which that vocation may demand of him, makes him unable to select his course of study wisely for himself.

He therefore goes forth, well equipped with a knowledge of theory, and acquainted to a good degree with what has been already accomplished, so that he need not spend his time in striving after impossibilities, and can reap the advantage of other mens' progress. How often has some man of limited information found, after months of work and investigation, that the problem which he has been striving to solve, has been worked out before by some one else, with perhaps a more satisfactory result! The graduate then, of our best technical schools, instead of climbing painfully, step by step, the ladder of personal experiment and investigation, to find out each truth for himself, is, if the metaphor may be continued, taken up by an elevator whose cost is defrayed by public or private beneficence, and is started out in life from the higher vantage ground of others' knowledge. Let us hope that, through inaction on the way, his legs may not have become too weak, nor from his sudden elevation his head become too giddy to bear and guide him successfully when he is thrown on his own resources.

Herein lies one weak point of our scientific training, a too rapid accumulation of information. A mass of dry facts and details will not stay in a pupils' mind; unless he has an opportunity to verify statements experimentally, to see, so far as is possible, the classes of engineering work to which his theoretical study refers, and to go through such operations and make such designs as are practicable, and as accord with the usual field and office work of an engineer, he might as well not have been crammed with a mass of information which he has not had time to digest. Then the young graduate lacks experience. What some consider the *practical man*, is one who is all experience and no theory; such a man we consider about as bad at the present day, when any progress is desired. No steady patterning after previous examples, or following "rule of thumb," will enable us to advance. A happy union of theory and practice is what is found in the best men of the profession.

Another source of weakness with some young men is over-confidence. Too great attention, perhaps may have been paid in their scientific training to the pure mathematical calculations, and too little weight given to elaborating details. Computations and investigations carried to great length, tend sometimes to make us forget the premises and assumptions upon which they are founded, and it is proper then to review the work, examine the base upon which we have built, and see whether it is worth while to cipher with seven-place logarithms, and carry out results to several places of decimals, when the whole calculation may depend upon a breaking strength, a modulus of elasticity, an angle of repose, or some other constant of the material with which we deal, which is only an average value and stated in round numbers. Why use a large factor of safety, and then determine the cross-section of a piece to a small fraction of an inch? Still, if we do not use the mathematically correct results, we are not advocating guessing. We would strike a happy mean between pure theorizing and arbitrary rules.

The habits of caution and circumspection which old engineers possess the rising generation are prone to term old fogyism. But such habits they will, if they ever do much work, and profit by their experience, acquire themselves. We are all liable to make mistakes. If they are of any importance, if they entail any expense, we are not likely to forget them, and to repeat them. We are better taught by such m shaps than by all our successes, but such teaching is very expensive. The engineer of good judgment soon learns to view with exceeding care, results and proportions which a common sense view of the case would hardly lead him to expect, and he also appreciates the fact that the weakest detail in a structure determines its power of endurance.

A masonry culvert may be substantially built, but a weak spot of limited extent in the foundation may be searched out by the water at a time of flood and be the cause of the failure of the structure. An apparently well-built bridge, may, from the weakness of one or two floor timbers, of poor stock or hidden defect, not seen on casual inspection, be completely wrecked, on the breaking through of a train. We have not endeavored to present the need of caution in an engineer on the ground that he is intrusted with the carrying out of works on whose faithful construction depend many human lives, for this branch of the subject is so evident as to appeal to all without words of ours.

The young engineer then starts out under favorable auspices. He has a good scientific training, zeal, energy, and perseverance; he must, to do well, be ballasted with prudence and caution in applying his talents to the work of bending the powers of Nature to the service of man. In that case we can fitly close with the words of the letter which we recently quoted, and which suggested these remarks,—"With such advantages, if young America does not soon supercede old America, it will be, not from the want of power, but from lack of its proper use."

THE ASHTABULA DISASTER.

The month of December 1876 will be remembered as replete with disasters almost unparalleled in this country, resulting in terrible loss of life. First, the Brooklyn holocaust,—then the wreck of the Circassian on the shore of Long Island resulting in the death of nearly thirty persons, and last the fatal plunge of the Pacific Express through the Ashtabula bridge on Friday night Dec. 29th.

The incidents of this most recent accident are already familiar to our readers through the daily press and it is not our province to repeat them here. The bare facts are sad enough without any reportorial coloring. As to the cause of the accident all is as yet surmise, and but little satisfaction can be derived from the meagre evidence at hand, and from the conflicting and too often pernicious accounts of the daily papers which deliberately charge,—on the wildest rumors and vagaries,—railway officials and all connected with the accident with the most derelict attention to duty and culpable carelessness both before and after the catastrophe. These sentiments even creep into the editorial columns of our papers and we notice in one of our morning dailies a wholesale condemnation of the entire class of iron bridges. The writer of the article in question should know better. Sufficient to say that there was a cause, and that probably it will be found out in due time and satisfactorily explain the failure of the bridge, although that will not recoup the loss of life.

We write this week not because we have any satisfactory explanation to offer but in order to lay the data for an opinion, so far as known, before our readers and dispel some of the illusions which have possessed the public mind.

Last Friday, day and night, Dec. 29th, was noted along the Lake Shore road and farther east for its unusual snow fall, followed by a severe, cutting wind, which piled it up in drifts making railway travel extremely difficult and vexatious. Trains were delayed on nearly all the eastern roads and on some were entirely blocked. The Pacific Express on the M. S. & L. S. R. R., consisting of two engines, four baggage and express cars two ordinary coaches, one smoking car, one palace car and three sleepers in the order named, left Erie at 5:01 P. M., 1 h. and 8 m. late and was due in Ashtabula at 5:15 P. M. After working through the snow it arrived at Ashtabula bridge, a few hundred feet from the depot, at about 7:30 P. M., and with a velocity of 10 to 12 miles per hour

When the head of the train had nearly reached the farther end of the bridge this structure gave away, from some cause not known, and the entire train, excepting the forward engine which crossed in safety, was precipitated into the ravin · of Ashtabula Creek, falling about 75 feet, and in a short time thereafter being entirely consumed by fire. The number of passengers on board has been variously estimated at from 130 to 300. According to the testimony of the conductor there were 160 when the train left Buffalo, and at the time of the accident 138, exclusive of those who got on west of Buffalo, and those who held return tickets. The account so far as made out by the railway officials from collecting the tickets and comparing them with conductors' accounts, etc., gives the list as follows:—

	Whole No.	*Killed.*	*Saved.*
Passengers	137	*80	57
Train men	12	*7	5
Employes	4	2	2
Expressmen	3	1	2
Children	2	2	0
Total	158	92	66

*Two passengers and one train man, who died after being rescued, are included.

The bridge was a double track, deck or over grade structure, a single span of 157 ft., Howe truss type, built in iron, having two truss systems. It was built about eleven years ago at the Cleveland shops of the Lake Shore Company before its consolidation with the Michigan Southern, and during the presidency of Amasa Stone, and was designed by John Towlinson now Director of Canadian lighthouses. We believe that it was considered entirely safe by Mr. Collins now Chief Engineer of L. S. & M. S., a man who has the reputation of being one of the most careful railway engineers in this country and the most exacting in all the requirements for permanent structures.

Mr. Chas. Paine, Gen. Supt. of L. S. & M. S., and Chief Eng. of the Michigan Southern previous to the consolidation with the Lake Shore, a man everywhere regarded as of the utmost probity and ability has been on the ground ever since the accident and from his report, when made, and the result of the coroner's inquest we shall be able to frame an opinion, if not entirely satisfactory, at least above criticism.

Not enough is known as yet to form even a tentative opinion. So far as the bare evidence before the coroner's jury is concerned, it appears that the forward locomotive was, as variously stated, from two car lengths to 45 or 50 feet from the farther end of the bridge, and and that the engineer of the forward locomotive feeling either a sinking of the bridge or a dragging of the trucks behind as if off the track, suddenly pulled the throttle wide open, his engine in the meantime appearing to go up grade; the coupling connecting his tender with the following engine was broken, presumably at the time the throttle was pulled wide open, and his engine escaped to the farther abutment, running some 150 feet before coming to a stand still, the four wheels of the rear truck of the tender being derailed as it struck the abutment apparently by the swinging of the bridge to one side He says he undoubtedly felt the bridge sink apparently in the middle. The second engine was pulled forward and struck the abutment with a great crash. Other evidence seemed to support his general statement. One passenger who escaped from the smoking car said he felt that the trucks of that car were off the track, but this is of no value for the reason that the smoking car was not upon the bridge at its initial fall.

The train was upon the left hand track and in the wreck the cars appeared to be thrown some 30 feet to the left of the center line of the bridge. As to the manner in which the bridge was decked, if decked at all, whether or not the cross-ties ran through and through from one track to the other, their dimensions, distance apart, whether or not they were so fastened apart by blocks or otherwise as to prevent them from being winrowed by a broken or derailed truck, the character of the floor-beams and the upper sway bracing, guard rails,—all necessary to a correct judgment of the immediate cause of the accident, we have no information.

The fact that the bridge must have been designed for a train of locomotives occupying each track at the same time, that it was tested by a train of six locomotives soon after its erection, that heavier trains must have crossed the bridge within a few hours, that probably in the great number of trains which are constantly crossing the bridge in both directions, two must have been upon it at a time quite recent,—all combine to preclude the idea of its falling from any intrinsic weakness of the structure itself, in its various parts.

The idea of its being weakened by a low temperature or from crystallization or disintegration of the structure of the iron from repeated strains does not merit serious attention at the hands of engineers. So far as any experiments that have been made give any grounds for a conclusion in regard to the effect of low temperature on iron, it seems to increase its resistance somewhat for a static strain and diminish it for a blow; metals rendered cold-short by the presence of phosphorous or other elements seem to be weakened by a low temperature. As regards weakening from repeated strains the evidence is not conclusive, experiments indicating that it is not weakened at all if the strains are within the elastic limits. The toughest iron broken by a blow gives a crystalline fracture, and much of the evidence for crystallization [which can only take place near the melting point] is based on this peculiarity. A year ago the Illinois Central railroad engineers took several bars from bridges which had been erected 13 years, and when tested they appeared as strong as when first put into the structures.

If no farther evidence were forthcoming our theory of the disaster would be:—Some of the wheels or trucks of the first tender, the second engine or tender or the first car became derailed in the snow east of the bridge, and on striking the cross-ties of the bridge with a succession of blows or gathering them up in a pile, plunged through breaking floor-beams and cross-bracing; the farther truss would be pulled in and the whole structure would cripple, meantime the top swinging bodily to the left the bridge overturning upon its seat. If the train became derailed in any manner on the bridge the probability is that it would go down however strong. This explanation seems consistent with the evidence so far as given, but we only offer it provisionally in the absence of facts necessary to a sound conclusion. The above theory seems to accord with the impressions of the engineers as expressed at the informal discussion at the Engineers' Club on Tuesday, and with that of various bridge and railway engineers with whom we have talked since, although all prefer to withold their judgment until farther evidence is shown.

This accident is quite similar to one which occurred on the Union Pacific on the Plains, the week preceding Christmas. The through passenger train bound east went through a trestle sixteen feet high. The engine we believe crossed in safety. Four cars went through all of which caught fire and burned; but fortunately beyond some severe bruises, every one but two or three escaped with their lives. Afterwards it was found that an axle of the forward car had broken a quarter of a mile or more back, the marks of the derailed truck being plainly discernable upon the ties. On striking the trestle the ties were winrowed before the broken truck until the strain was too great for the coupling connecting the car with the tender, which breaking, the rails meantime being unsupported, the whole train fell through and was wrecked.

Several other accidents in regard to bridges are in our mind which are peculiarly instructive at the present writing, but we shall defer them for a more opportune time.

THE NICARAGUA CANAL.

REPORT OF THE COMMISSION.

Gen. Humphreys, chief of engineers, Superintendent Patterson, of the coast survey, and Commodore Ammen, chief of the bureau of navigation, who were appointed a commission by the president to examine and report upon the surveys and projects submitted for the inter-oceanic canal across the Isthmus of Darien, completed their labors on the 26th ult, and sent the following report to President Grant:

1. That the route known as the Nicaragua route, beginning on the Atlantic side at or near Greytown, running by canal to San Juan river, following it by slack-water navigation to Lake Nicaragua, across the lake to Rio del Medio, and thence by canal to Rio del Brito on the Pacific coast, possesses both for construction and maintenance of canal greater advantages and offers fewer difficulties from engineering, commercial, and economical points of view, than any of the other routes shown to be practicable by the surveys, sufficiently in detail to enable a judgment to be made of their relative merits.

2. The summit level of this route Lake Nicaragua, is designed to be kept 100 feet above the level of the sea. This height is to be overcome on the Atlantic side by four dams in the San Juan river and 10 lift-locks, and on the Pacific slope by 10 lift-locks. The total distance from the Greytown end to that at Brito is 181 miles. Of this distance the Atlantic slope division from Greytown to San Carl s at Lake Nicaragua comprises 108 miles, of which 63 are by slack-water navigation and 45 by canal. The summit level division comprises 56 miles by Lake Nicaragua from San Carlos, at the head of the San Juan. to Rio del Medio. The Pacific slope division comprises 16 miles by canal from the mouth of the Rio del Medio to the mouth of the Rio del Brito. The dimensions of the locks proposed are 400 by 70 feet with 26 feet of water. Artificial harbors must be constructed at Brito and near Greytown, and although that at Greytown presents unusual features requ ring careful study and skillful treatment, there is no question of its practicability.

3. That the cost of the construction of this canal and harbor with all necessary adjuncts will be at least $100,000,000, and that the cost by any other route will greatly exceed the cost by this route.

4. That all preliminary arrangements having been made, the time required for actual construction should not exceed 10 years.

5. That an inter-oceanic canal across this continent should be under protection of all the nations interested, and that they should guarantee not only the neutrality of the canal and its works, but also of the continuous strip of territory on each side of not less than 50 miles in breadth, and of ocean approaches of not less than 100 nautical miles in any direction along the coast and out seaward from each end.

The President has communicated upon the subject with the leading maritime nations of Europe and has received favorable responses from a number of them. As soon as all shall have been heard from he will submit the whole matter, including the reports and corre spondence to congress, by special message. The indications are thought to be favorable for an early commencement of work upon the proposed canal.

We learn later that a new treaty has been consummated between the U.S. Government and that of Nicaragua in regard to the ship canal which will probably be transmitted to and confirmed by the Senate ere this reaches our readers. It provides for the construction of a canal from the Atlantic Coast at or near Greytown to the San Juan river, following it by slackwater to Lake Nicaragua, across the lake to Rio del Medio, thence by canal to Rio del Brito on the Pacific coast. The length of canal requiring excavation is 61 miles and the total estimated cost is $50,000,000.

The Nicaraguan government concedes neutrality rights; i. e., the neutrality of a specified width of territory on either side of the route, a certain length of seacoast necessary for harbors and the neutrality of the canal, extending 100 miles to sea. The ports of Greytown and Brito are declared free. In the event of war between Nicaragua and any government interested in the construction of the canal, all other governments are to be exempt from capture, blockade or other embarrassment so far as the canal is concerned.

The United States in conjunction with other powers, when the canal is completed, are to guarantee full protection from seizure or confiscation and also the neutrality of the work, so that the canal shall be forever open and free, and all capital invested secure. These guarantees are however to be withdrawn in the event, if the management is contrary to the treaty stipulations. The property of parties engaged in the construction of the canal is to be protected by the local government and the construction of the work is to be urged with all the influence of the United States and other interested powers.

The leading maritime powers of the globe are to be invited to participate and share in the construction of the work, and to enter into treaty stipulations to that effect. The canal is to be open to citizens of all nations participating in its construction on equal terms. The construction of the canal is to commence at the earliest practicable moment. Foreign governments have been notified of the intended action of our government.

In the absence of the detailed report of the Commission which recommended the Nicaragua route, it is impossible to review intelligently the grounds of its selection. The high character of the men on it, however, entitles it to all respect. Our own views as previously expressed inclined us to favor a farther examination of

the Panama route, at or near the site of the Panama railway, which is much shorter, has equally good harbors and as low a summit level, and, we believe can be constructed with equal cheapness. This route may have been precluded from consideration by treaty at the time of the railway's construction, which treaty, we believe, was framed with direct reference to the contingency of a canal. In the mean time the Columbian government has been now for a year or more endeavoring to attract attention to the route by Cacarica Pass and the Rio Tuyra, certainly one of the most impracticable of the many yet examined. Members of the French Geographical Society have also been advocating this route and endeavoring to organize an international commission to examine, survey and investigate all the routes across the Isthmus, apparently ignoring all the excellent surveys and reports made by American engineers, and expeditions sent out for that purpose, or, exhibiting a most profound ignorance in regard thereto. Hence, from that government at least, we shall expect a considerable exhibition of brake-power, until the construction of the canal is thoroughly assured and under way, and then an astonishing alacrity to join in the enterprise. Other governments, we have reason to believe, will join heartily in its construction.

As regards the Nicaragua route so far as this government is concerned many things may be said in its favor, and may have had weight in making up the decision of the board. The same considerations would apply with greater force to the Tehuantepec route, and were equally practicable in an engineering point of view. From the Atlantic ports to the Pacific ports of the U. S. and the ports on the west coast of Mexico, it is nearly a thousand miles shorter than the Panama route and considerably more than a thousand miles shorter than the route via the Tuyra river or the upper Atrato; and the distance to ports on the west coast of S. America is but slightly increased to American shipping. Considering the magnitude of the coasting trade that must necessarily spring up between the Atlantic and Pacific states, this is a consideration of no small force. The distance from Pacific state ports to foreign ports, to which their grain is largely carried, would not differ materially by any of the routes. Hitherto the grain fleets have left San Francisco for Liverpool via Cape Horn, landing their freight in the latter city at a cost but a very few cents per bushel in excess of the cost from Chicago to Liverpool during the prevalence of the late low summer rates. With the completion of this canal San Francisco can lay her grain in Liverpool or any other foreign port as cheap if not cheaper than can Chicago. So as a result of the canal the Pacific states will be able to compete with the valley or interior states in the foreign market, the Atlantic states will establish steamship lines to western S. America, Australia, New Zealand and China, and it will also be the shortest route from Great Britian and aujoining nations to the same countries. The Nicaragua Canal will be a greater national evangelizer than the Suez Canal can hope to be under the narrow sectional policy of Britain.

NEXT week we will commence the publication of a series of articles on "Arches; Considered Graphically," by Prof. Chas. E. Greene, which will be a continuation of the series on Bridge and Roof Trusses already published by the same author.

WE notice that the Mississippi Central and the New Orleans, Jackson & Great Northern Railways, 455 miles, have passed into the control of Illinois Central and been consolidated therewith, making a continuous line of 910 miles from Chicago to New Orleans. Mr. J. G. Clarke, General Manager of the Illinois Central, is made second vice-president, and specially charged with the care of the New Orleans line with probable headquarters at New Orleans.

DURING the past year we did not carry any back numbers of ENGINEERING NEWS for future sale. Neither will we do so this season, and as valuable papers both original and selected will hereafter be published in our columns more frequently than in the past, so it will be apparent that to secure a complete set an immediate subscription will be advisable. At the same time we wish it understood that the pages of "Sanitary Engineering" are stereotyped and may be had at any time during the year, although the price of the bound volume when completed will be more than our regular subscription rates. After the completion of "Sanitary Engineering" the sheets comprising it can only be had at an extra price.

CORRESPONDENCE.

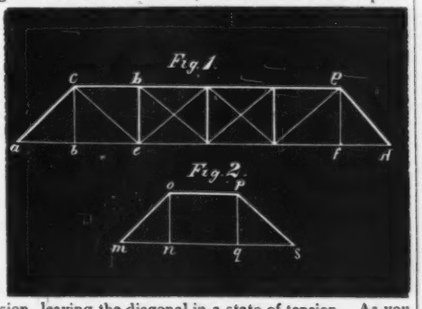
BRIDGE DESIGNING.

Editor ENGINEERING NEWS:

In your paper of December 16th I find an article on "Bridge Designing," which arrives at conclusions which appear to me erroneous. A truss is described as "of the Pratt type, 72 ft. span, 9 ft. high, 6 panels, the top chord running but four panels, so that the sloping members at the ends are struts, and the first verticals are suspending rods. Load on bottom chord."

The diagram, Fig. 1, represents such a truss.

The query is put: "If a live load of 7,200 lbs. hangs by the first vertical, in what manner will one-sixth of it pass to the further abutment?" If I correctly understand your position, it is, that the strain from the load at the bottom of *b c*, Fig. 1, being a vertical one, cannot strain a horizontal member like the top chord *c g*, and (quoting from your article) "the only course for that strain in its movement toward the further abutment, is down the diagonal in the second panel (*c e*). For this load alone the strain on the diagonal would be compression, and, as this member is intended to be a tie, it would carry but very little thrust." Then you state that the steady load on other parts of the truss, produces a tensile strain on the diagonal *c e*, which, being the greater of the two strains, overbalances the compression, leaving the diagonal in a state of tension. As you say nothing of the further movement of this compressive strain, it seems you consider it annihilated by the greater tensile strain, without ever reaching the further abutment toward which it started.



Now, in Fig. 2, a load which is carried by the vertical *n o*, must certainly produce a strain in the horizontal straining beam *o p*. Two-thirds of the load on *n o* will pass down *o m* to the nearer abutment, while one-third will pass along *o p* and *p s*, to the farther abutment, and the truss will not fail except by the rising of the point *p*, which will be prevented by placing an equal load on *p q*, or, by inserting counters. I cannot conceive how the insertion of a tie in the diagonal *o q* could in any manner change the course followed by the strain in passing from *n o* to the abutment at *s*. Now in Fig. 1 suppose all the web members, except *b c* and *f g*, to be removed, the truss would then be in a precisely similar condition to Fig. 2. It seems to me very plain that one-sixth of any load supported by the tie *b c*, must necessarily pass along the whole length of the top chord, and down the strut *g h* to the further abutment, while five-sixths of it passes down the strut *a c* to the nearer abutment, thus following the same course as a load carried by *n o* in Fig. 2, or by *b c* with all web members removed except *b c* and *f g*.

If my views are wrong I shall be very glad to be corrected by some of your correspondents, or by yourself.

A. H. B.

LITTLE ROCK, ARK., *Dec.* 26, 1876.

We are rather surprised, and not a little amused that anyone should suppose we considered the compressive stress, which a weight at *b* would cause in the diagonal *c e*, to be so thoroughly annihilated by the tension in that same member as to have no effect elsewhere in the truss. As the designers of strain sheets previously referred to seemed to insist on carrying it over the top chord, we thought that, if we once got it successfully upon the tie *c e*, there would be no need of tracing its progress to the abutment at *h*, for which it was bound. Besides, as, in each of the middle panels, we had a choice of two diagonals, it would depend on the distribution of the rest of the load, steady or rolling, which diagonal would be in action. As the original problem did not specify this point, we did not trace the stress beyond *c e*.

As to our correspondent's Fig. 2,—If "the insertion of a tie in the diagonal *o q*" will not "change the course followed by the strain in passing from *n o* to the abutment at *s*," why put in *o q*, which, by the way, would then be a strut and not a tie?" It seems to us that our subscriber proves too much. We cannot see, if we adopt his reasoning, why, by a slight modification of his design, he might not leave out all the counters (of which his sketch had four), and, possibly, do away with bracing altogether. Then suppose the truss had vertical end posts:—the one-sixth of the weight at *b* would of course then go by the bottom chord, for we should have no strut *a c* to compress the top chord, and we should find that an alteration in a member at one or both ends of the truss had changed the amount of stress in portions say at mid-span, something which cannot be true.

We would suggest that A. D. B. study over Fig. 2 a little more, considering the action of a partial and unsymmetrical load.—[ED.

CIVIL ENGINEERS' CLUB OF THE NORTH-WEST.

The 71st regular meeting of the Club was held at the Sherman House Club Rooms on the 2d of January, 1877, beginning at 4 P. M.

The President, Mr. E. S. Chesbrough, not being present, Mr. Blunt was called to the chair.

The minutes of the December meeting were read and approved.

The Secretary reported a donation from the Union Iron Company, of Buffalo, N. Y., of the latest edition of the "Book of Shapes" issued by that Company.

Ballots were cast for the following gentlemen proposed as members at the last meeting: J. W. Weston, W. F. Goodhue and C. G Artingstall, resulting in their election.

Mr. Roney stated that Mr. Henry Gannett was now engaged by the Department of the Interior in extending the work begun by Mr. James T. Gardner, of obtaining data to determine the elevation above the sea of as many points as possible in the United States, and that Mr. Gannett would be obliged to members if they would forward to him at Washington, D. C., any memoranda that would further his work.

(Mr. Chesbrough, having arrived, took the chair.)

Mr. Morehouse read the paper for the evening,—"Memoranda Concerning the Blasting of Ice in the Winter of 1875," also a letter from Col. F. A. Farquhar upon the same subject.

After discussion of the topic an informal discussion was had of the recent bridge disaster at Ashtabula. No member present having any personal knowledge of the bridge or of the accident, no opinion was expressed as to the cause of the failure of the bridge.

The meeting adjourned.

L. P. MOREHOUSE, *Sec.*

COAL GAS.*

BY WM. D. MARKS.

Distillation,—It is of the utmost importance to the gas manager to obtain from a given quantity of coal, the largest quantity possible of hydrocarbons which are gaseous at the ordinary pressure and temperature of the atmosphere.

To know how to obtain such result it will be necessary to discuss separately the constituents, so far as known, of coal gas and their behavior under the various circumstances in which they are placed during the process of manufacture.

Crude coal gas, as it comes from the retort contains about 14 known gases carrying with them in the form of vapor an unknown number of hydrocarbons which are condensed as tar and oil at the ordinary temperature of the atmosphere.

The gases may be divided into three classes.

1st. *Diluents.*

(H.) Hydrogen.

(C. O.) Carbonic Oxide.

($C. H_4$.) Carburetted Hydrogen.

The last named gas has for a long time been classed among illuminants, but experiments go to show that its illuminating power is *practically* nothing.

2d. *Illuminants.*

($C_2 H_4$) Olefiant gas. Also known as Ethyline.

($C_2 H_2$) Acetyline.

($C_3 H_6$) Propyline.

($C_4 H_8$) Butyline.

There exists besides, a very large number of gaseous hydrocarbons whose composition and properties are not yet known.

3d. *Impurities.* By impurities are meant all such gases or vapors as are, or ought to be, removed before the gas is delivered to the consumer.

They are as follows:

($S H_2$) Sulpuretted Hydrogen.

($C O_2$) Carbonic Acid.

($S_2 C$) Bisulphide of Carbon and perhaps some other organic sulphur compounds.

($N H_3$) Ammonia.

(C N) Cyanogen.

[S (C N)] Sulphocyanogen.

(O) Oxygen.

(N) Nitrogen.

Tar or liquid hydrocarbons which have been vaporized and thus carried along with the gas.

Diluents. Hydrogen is formed during the distillation of coal in very variable quantities, by the decomposition of water mechanically contained in coal, which is converted into steam and decomposed into Hydrogen; Carbonic Acid gas is formed by the red hot coke with which it comes in contact in the retort, and the same result is obtained when coal tar and steam meet in a red hot vessel.

Water absorbs 1.56 per centum of its own volume of this gas; it is not affected in any way by lime, and it burns with an intense heat giving very little light.

One cubic foot of (H) hydrogen when burnt consumes ½ cubic foot of (O) oxygen, generating 1 cubic foot of steam, and gives heat enough to raise 1 lb. 13 oz. of water from 32° to 212° F. $2H + O + N = H_2O$.

Carbonic oxyde is generated simultaneously with Hydrogen by contact of red hot coke or tar with steam or by combustion of Carbon in a limited quantity of oxygen, carbonic acid being at the same time produced. The relative amounts of carbonic oxide, and carbonic acid vary with the temperature of the retort, at a white heat carbonic oxide alone being produced.

Water absorbs 1.56 per cent. of its own volume of this gas and it is not in any way affected by lime. It burns with a greater heat than hydrogen, giving a blue flame and very little light.

One cubic foot of carbonic oxide when burned consumed ½ cubic foot of oxygen generating 1 cubic foot of carbonic acid and giving heat enough to raise 1 lb. 14 oz. of water from 32° to 212° F. $CO + O = CO_2$.

Light curburetted Hydrogen is a direct product of the destructive distillation of coal and seems to be produced under a wide variation of temperature. When subjected to a white heat it is slowly decomposed giving twice its volume of hydrogen, and depositing carbon.

When allowed to burn in a large thick flame with light pressure, it gives considerable light. Under great pressure and issuing from a small orifice it gives little or no light. This is a peculiarity also with all the gaseous compounds of hydrogen and carbon and the amount of light derived from ordinary coal gas is dependent in a great degree upon the pressure and size of the orifice from which it issues.

Water absorbs 1.6 per cent. of its own volume of this gas and it is not affected by lime. When burnt one cubic foot yields heat capable of raising 5 lbs. 14 oz. of water from 32° to 212° F.

1 cubic foot consumes 2 cubic feet of oxygen, generates 1 cubic foot of carbonic acid and 2 cubic feet of steam. $CH_4 + 4O = 2(H_2O) + CO_2$.

About 94 per cent. of the volume of purified coal gas consists of the diluents above described. Of these light carburretted hydrogen forms about 33 per cent. of the whole volume of gas, hydrogen and carbonic oxide making together about 60 per cent. These feebly luminous gases serve as the vehicle of the remaining 6 or 7 per cent. of illuminants.

Illuminants.

Olefiant gas or Ethyline, is generated at a high heat, and is a heavy gas, water absorbing 12.5 per cent. of its own volume of it. When subjected for any length of time to a full red heat it is decomposed, hydrogen and perhaps light carburretted hydrogen being produced and carbon deposited. Lime does not affect it. When burnt it gives a brilliant white light without smoke, 1 cubic foot consuming 3 cubic feet of oxygen and generating 2 cubic feet of carbonic acid besides 2 cubic feet of steam. $C_2H_4 + 6O = 2(CO_2) + 2(H_2O)$

Acetylene, is generated at a very high heat; its solubility in water is not determined but it is probably greater than that of olefiant gas. It has been produced by the passage of the electric spark between carbon points in hydrogen gas, is very stable and does not deposit carbon in the retorts, and when united with less highly carburetted gas, burns with a white smoky flame.

1 cu. ft. when burnt consumes 2½ ft. of oxygen, generating 2 cu. ft. of carbonic acid and 1 cu. ft. of steam.

$C_2H_2 + 5O = 2(CO_2) + H_2O$.

Propylene, also called Tritylene, is best produced at a high heat, but is rapidly decomposed at a red heat.

Water absorbs about 12½ per cent. of its own volume of it, and it burns with a brilliant flame, giving 1½ times as much light as Olefiant gas.

1 cu. ft. consumes 4½ cu ft. of oxygen generating 3 cu. ft. of carbonic acid and 3 cu. ft. of steam.

$C_3H_6 + 9O = 3(CO_2) + 3(H_2O)$.

Butylene is produced by a heat which may vary from ordinary redness to that of the electric spark; it was first discovered in rancid butter, and is what gives the disagreeable smell to that substance. Like Propylene, it is rapidly decomposed at a red heat and in the absence of oxygen, depositing carbon; its solubility in water is not known, but it burns with a brilliant flame, giving about twice as much light as Olefiant gas. 1 cu. ft. consumes 6 cu. ft. of oxygen generating 4 cu. ft. of carbonic acid and 4 cu. ft. of steam.

$C_4H_8 + 12O = 4(CO_2) + 4(H_2O)$.

Owing to the extreme difficulty of investigating their properties and composition but very little is known of the illuminating hydrocarbons, and there is doubtless a large number besides these which we have so imperfectly described.

Impurities Sulphuretted hydrogen is derived from the iron pyrites found in greater or less quantities in all coal, the pyrites yielding one atom of sulphur to the nascent hydrogen. It is generated at all heats above red when oxygen is not present. Water absorbs about 2½ times its own volume of this gas and lime forms with it Sulphide of Calcium, or perhaps a higher than the proto sulphide.

1 cu. ft. of consumes 1½ cu. ft. of oxygen generating 1 cu. ft. of sulphurous acid and 1 cu. ft. of steam.

$SH_2 + 3O = SO_2 + H_2O$.

Sulphurous acid is irrespirable and suffocating, and occasions violent coughing when breathed; it is also a powerful bleaching agent, injuring the bindings of books, frescoing on walls, and in the atmosphere it oxidizes to sulphuric acid, thus destroying the texture of such articles as may come in contact with it.

Carbonic acid is produced by the combustion of carbon in an excess of oxygen, or by the decomposition of steam by red hot carbon in the absence of oxygen. As the heat increases less carbonic acid is produced, carbonic oxide being the greater product. Water will absorb its own volume of it and for lime it has a very great affinity, forming ($Ca CO_3$) and being able to displace the sulphides of lime.

It is an incombustible gas and will put out fire; it is irrespirable and will not support life, although not so poisonous as usually thought to be, the poisonous effects credited to it being generally due to carbonic oxide. 1 per cent. of carbonic acid in gas will reduce its illuminating power 6 per cent., so that it is important to free gas from every trace of it.

Ammonia, is generated in the destructive distillation of coal or any organic substance containing nitrogen.

Water at 60° Fah. will absorb 78 times its own bulk of it and lime will take from its salts their acids, setting it on fire as a pure gas; it can not be burnt in the open air, but a small jet in oxygen will burn, producing steam and Nitric acid.

$2(NH_3) + 8O = 3H_2O + N_2O_5$.

Cyanogen and Sulphocyanogen are obtained in small quantities in the distillation of coal. They are somewhat soluble in water and are not decomposed at a high heat unless in the presence of iron, when they are resolved into their elements. Both immediately form salts with ammonia and are carried off in solution in the gas liquor, and methods have been patented for obtaining them from the liquor but have not proved to be practically profitable.

Oxygen and nitrogen are probably obtained by leakage in the apparatus for making gas; they are not eliminated by the process now used in puifying gas and are often the greatest source of trouble where a high standard of illuminating power is required.

When the gas leaves the condensers it usually contains about 1½ volumes of ammonia, 8 volumes of sulphurretted hydrogen and 25 volumes of carbonic acid in every 1000 volumes of gas. Several of the impurities unite with the ammonia forming salts; sulphuretted hydrogen formiug sulphide of ammonia and perhaps higher sulphides, of which there are a large number, Carbonic acid forms carbonate of ammonium; Cyanogen forms cyanide of ammonium; and Sulphocyanogen forms sulphocyanide of ammonium. Of these salts carbonate of ammonium probably forms the greater part as carbonic acid has a greater affinity for ammonia than Sulphurretted hydrogen, and exists in 8 times the quantity, these two impurities being almost the only ones which are in sufficient quantity to be noticed practically.

The nitrogen and oxygen are probably introduced as air while charging the retorts, or where the exhauster is used, through leaks which may occur in the main, leading from the retorts to the exhauster or in the retorts themselves.

Coal Tar consists of Naphtha, coal oil, and pitch, and each of these three substances consists of a number of compounds which have been only partially separated and examined by a most tedious process of distillation. They are very valuable in the trades and as they are becoming better known are put to a wide variety of uses, but being always sold by Gas Co's as Tar, they are of very little interest to the Gas Engineer.

The quality and quantity of gas obtained from any given coal depends in a large degree upon the precautions used in the process of manufacture, which will now be described, as commonly followed in the gas works of the United States.

The coal used must fulfill two conditions, the first of which is to give in sufficient quantity a good quality of gas free from an excessive quantity of sulphur; the second, is to give a coke which is capable of heating the benches to the proper temperature. To obtain a coal fulfilling both of these conditions is often impossible, and the engineer is obliged to resort to mixtures of different coals, possessing one or the other of the desired qualities.

Before introducing the coal into the retort it should be broken into lumps not larger than a man's fist, and slack cannot be used except where a high heat is obtained in the retorts as it cakes together, and is drawn from the retorts in an imperfectly distilled state.

The method of charging now most commonly used in large gas works is by means of an iron scoop which is about the length of the retort and contains the weight of coal used at one charge in a retort. After being filled it is lifted by three men, two placing a bar under the middle and the third grasping the handle; it is then raised to the required height and rapidly thrust into the retort, turned over and withdrawn, leaving the coal distributed throughout its whole length. After a few weeks practice the men become very expert and prefer it to charging with shovels, a method which is not used by many engineers at the present day as it is less expeditious.

(To be continued.)

*A Paper read before the Engineers Club of St. Louis, April 30th, 1873.

THE ASHTABULA DISASTER.

We have but little to add in the nature of evidence to what we wrote last week. The investigation of the coroner's jury has been for the most part on facts not immediately connected with the cause of the accident and the evidence brought before it has been quite unsatisfactory and often conflicting.

We notice further in the evidence of the engineer of the first locomotive that he heard the "sleepers" snapping. (Another report says that he heard the bridge snap behind him and saw the second engine sinking). The general evidence, so far as it relates to the bridge, seems to imply that it broke in the middle and went down bodily. This of course is so far mere opinion, formed at a time when the opinion of most men would be valueless.

The idea that the bridge broke suddenly with a loud snap as if some important member gave way, as a pin, chords, main ties, or posts, and went down immediately, is inherently improbable, and we would not consider the question had it not been seriously broached.

The train was moving at the rate of ten or twelve miles per hour, and at the time of the accident the first engine was from 45 feet to two car lengths from the end of the bridge. Thus the train was moviug from 15 to 18 feet per second, and even if the first engineer did pull his throttle wide open and break loose from the train he could scarcely have cleared the bridge in less than two seconds. On the sudden snap theory the bridge in that time would have been 64 feet toward the bottom of the chasm. So in whatever way the bridge gave way we are obliged to infer that it settled or overturned quite slowly at first.

Mr. Geo. M. Reid, Supervisor of bridges on the Lake Shore road, testified that he had made a specialty of bridge building and inspection for the past twenty-five years, that he personally inspects all the bridges on the road several times a year, and that he inspected this bridge in September last—had not seen the wreck. He found the bridge in good condition and thinks no defect could have escaped his observation. He had always regarded it as a strong, firm bridge and it had never required any extraordinary repairs. Had no theory in regard to the disaster,—had discovered loose bolts twice in inspecting the bridge.

Mr. A. L. Rogers, a carpenter in the employ of the Lake Shore road, had been delegated by Mr. Reid to inspect the bridge over Ashtabula creek from time to time. Inspected it last in October,—found it in good condition—had never found anything out of repair about the bridge—was foreman at the erection of the bridge—his work was inspected by Amasa Stone, then president of the company who took charge of the building of this bridge, Mr. Collins, chief engineer of the company, taking no part in its constructien—was aboard the train in the smoker at the time of the accident—did not think the train left the track before the bridge fell—his theory is that the "second engine jumped the track and threw the bridge out of line, weakening it, when the weight of both engines caused it to break."

This is all the additional evidence we have at this writing. On Monday of this week, the coroner's jury appointed experts to examine into the present condition of the bridge in order to determine the cause of the accident. It will probably be some days before their report is made up.

In the meantime we learn that the new bridge, removed from Cleveland, was completed on the 10th inst., tested, and the regular traffic resumed.

In addition to the above, we have learned that the bridge truss had a supplementary arch, as was common to the earlier forms of Howe truss, and that it was erected to take the place of several wooden Howe truss spans, all the space, except that to be occupied by the iron bridge, having been filled in with bank. Mr. A. L. Rogers, who was foreman at the erection of the bridge, says his work was inspected by Amasa Stone, and that "during the first two months after the bridge was built, before it was used, it settled six inches by its own weight. It was raised with great care, and retained its proper position with a camber of about six inches. The false frame was removed in November, 1866. It was then pronounced perfectly safe."

The New York *Herald* reports, on what it considers reliable authority, that when Mr. John Towlinson, now director of Canadian lighthouses, submitted the plans to Mr. Amasa Stone, then president of the road, Mr. Stone insisted upon some material changes in the plans, to which Mr. Towlinson strenuously objected, declaring that he would not hold himself responsible if the proposed changes were made. "The bridge was erected on the modified plans, and when nearly completed, it was found that the structure was too short to span the space between the piers, and for three months the work remained untouched. At the end of that time the bridge was completed. It was built in the car shops of the company."

As the bridge was built over ten years ago, it is possible that considerable cast iron may have been used, as was common even in bridges of later date, and that it was designed for a lighter running load, the weight of engines commonly used having materially increased in the past few years. It is but a few years since all the iron bridges on the Erie R. R. were removed, as a measure of safety, and replaced by stronger and more modern structures, owing to the increased engine weights which had come into use. This move, we believe, was not suggested by any accident, but only as a needful precaution.

We note a curious coincidence in connection with the Ashtabula disaster. The train left New York at 8:30 P. M., arriving at Albany at 1:30 A. M,. when it split, one part going north to Montreal, and the other going westward to its fate at Ashtabula. The Montreal train went through a wooden bridge 150 feet long, spanning Otter creek, near Pittsford, Vermont, and was wrecked, we believe, without loss of life.

Numerous minor accidents have been reported from all parts of the country, due in a measure no doubt, to the increased inte est excited by the Ashtabula accident, and possibly an actual increase from the remarkably severe winter weather that has everywhere set in so suddenly. Among them we notice that a passenger train on the Kankakee road ran off the track last week on the bridge over the Kankakee river. The cause was a broken rail on the bridge. No particular harm was done except that one passenger was thrown through the car window, receiving some scratches.

The Angola accident has not yet passed from memory and was regarded at the time as almost without parallel. It occurred about 3:30 P. M. of Dec. 18th, 1867. The weather had been very cold and considerable snow was on the track. The east-bound train passed Angola station about twenty-one miles west of Buffalo on the Lake Shore road, at a speed of twenty-five miles per hour, being some two hours late. As the train left the double track the broken flange of a wheel of the rear car caught the frog, the car was derailed and went bumping along over the ties. An attempt was made to stop but being on a down grade and the track slippery before the train could be brought up, the rear car swung over the bank at the Big Sister creek, and making a complete somersault, crashed down to the frozen stream forty feet below. The car next before rolled down the opposite side of the embankment twenty-five feet and rested on its side.

The first car that jumped the bank, ended over, piling the passengers down on the stove, and finally fell over on its side, catching fire almost immediately. It is supposed that there were over fifty passengers in this car only three of whom escaped. The second car caught fire twice and was finally extinguished. Fifty-two are known to have been killed in all or died of their injuries, and the total number of killed and wounded reached nearly a hundred.

THE NEW YORK CANALS.

The Canal question is likely to come prominently before the New York Legislature. The business of the main lines has shown a great falling off, and, although the tolls have been low, a still further reduction is asked for. The Buffalo Board of Trade has asked that only sufficient tolls be taken to provide for the repairs, thus cutting off the State from any prospect of revenue. This request is an admission that the canals have failed to do what was expected of them. A writer states: "The constitution, as adopted in 1846, provided that, after paying all ordinary expenses of the canals, there should be set apart annually $1,300,000 of the surplus canal revenues until the year 1856, and after that $1,700,000 a year, as a sinking fund to pay the canal debt; that after complying with this provision, when the canal debt is paid, $1,500,000 shall be set aside annually from the surplus canal revenues for a sinking fund to pay other State debts; and that, when this provision also is complied with, there shall be paid annually out of surplus canal revenues $200,000 to defray expenses of the State government; the remainder to be applied for enlarging and finishing the canals. Now, thirty years after the adoption of these provisions, during which the State has paid about $15,000,000 in direct taxes for canal purposes, we find an unpaid canal debt (according to the last report) of more than $8,000,000, the canal revenues decreasing, and canal interests calling on the State for help, instead of helping the State themselves."

The management of the canal ring is one of the causes of this condition of things, a cause which is now probably removed. The railroad war of the last season brought freight charges so low as to be most damaging to lines of water carriage, with their slow speed and hence great loss of time. The lateral canals have been a burden. The partial introduction of steam canal boats has not turned out favorably: not because they did not work to advantage and without injury to the canal, but because business was lacking.

If the canals cannot be made to pay their own expenses, it is suggested that they should be sold. No business man would retain property on which he was experiencing a continual loss, and if careful and economical management by the State cannot make them pay, they ought to be disposed of to parties who might believe they could make them do so, if such persons can be found.

THE frightful accident at Ashtabula has aroused the public to the belief that efficient measures ought to be taken to better provide for the safety of railroad travelers. We notice that at Columbus, Ohio, a joint resolution was introduced in the legislature, instructing the governor to appoint three competent engineers to inspect the prominent railroad bridges of the State, and was laid on the table to be discussed. At Washington, Mr. Wilson, of Iowa, offered a resolution requesting the Committee on Railroads to take into consideration and report whether it is wise and expedient to provide by law for the appointment of a National Board of Engineers, to supervise the construction of inter-state railroads, so far as safety to travelers is concerned. The expediency of urging such action as this was discussed at considerable length by the American Society of Civil Engineers some two years ago, and several of its members strongly advocated such a step.

OUR 'Specially to Land Surveyors" has created no little stir among our brethren of the compass and chain, and we have received more valuable hints for our future guidance within a week than for the whole of the past year. The tenor of the article in question has been somewhat misunderstood—the word "contempt" as applied to any class of community that lives by honest labor is not in our vocabulary. Much less is it as applied to the profession from the practice of which we have personally, drawn a very fair income for the past thirteen years, or to the great body of the intelligent, conscientious, and industrious members of that profession, with many of whom we are personally or by correspondence acquainted. We simply stated our experience as a publisher, and if a feeling of disappointment added a little gall to our thoughts as expressed, it does not change the facts. We are satisfied, however, that it will have a good effect all around—we know that we have learned something about our own shortcomings, of which we might have otherwise remained in blissful ignorance but for the "stirring up" we have given to certain of our readers; on the other hand, we hope it will not be forgotten that we are publishing a paper to *make money*, and that very naturally our energies will be directed especially in the direction from which we hope to draw the greatest amount of that very convenient commodity. We now think that from what we have learned in the past week, and what we will most likely learn in a week or two to come that we can make ENGINEERING NEWS truly a surveyors' paper at the same time that we make it particularly a *business* journal, one that will commend itself to the classes for whose benefit we have especially designed it.

THE governor of New York in his message does not see the utility of a *State survey*. He cites, among instances of a pernicious mode of legislating, the provision in the supply bill of the last session for instituting and organizing "an accurate trigonometric and topographical survey of the State." "Without any application by the people," he says, "with no appreciable evil to remedy, with no practical inconvenience in the experience of a hundred years, and at a period of great pecuniary embarrassment, a plan is enacted in an appropriation bill for embarking the State, against the wishes of its people, in a work which promises to run through half a century, and to cost an unlimited amount of money. The mode and the matter of the enactment are alike objectionable, and I recommend the prompt repeal of that portion of the supply bill."

While we do not expect that, with the possession of accurate plans of localities and of large tracts of country, surveyors and engineers will be dispensed with in those places, we do feel as if great advantages might be derived by the local and State governments from having accurate information within their reach. As to getting along without any further services from our profession we are reminded of certain prominent and sanguine citizens of an Eastern place who, upon inspecting a very large and carefully made map of their city, expressed the opinion that, if any of the inhabitants desired to obtain information as to division lines, street lines, grades, etc., they would only have to call in at the City Hall and inspect the plan, and be at once posted on all points. We think there was even some talk of dispensing with the future services of the city engineer.

We have yet to learn that the Ordnance survey of Great Britain is considered and has been found by experience to be a useless expenditure of money. Whether the present time of financial depression is a good one for beginning such an undertaking may be a doubtful question; that it will take half a century to do what is desired, seems an exaggeration.

BARON VON WEBER has called attention to the curious state of things which will result from the construction of the Channel tunnel between England and France, in the way of causing great annoyance to English railway managers. The English railway system is a world of its own; on the completion of the tunnel, England will become a peninsula so far as the railways are concerned, as cars will pass from one shore to the other.

"If the importance of the object to be attained by the channel tunnel is to bear any rational proportion at all to the means required, the tunnel will be constructed only if a very considerable goods traffic between the two shores is expected, besides the passenger traffic. Such a traffic, which would have to compete with the sea carriage, is only possible for goods if shifting the loads is completely avoided, and the wagons and trucks can run from England far into the Continent and *vice versa*. Now the English exports to the Continent far exceed the imports from it. The English trucks, therefore, loaded with rails, machines, coals, cotton goods, etc., will, after passing the tunnel, be scattered far and wide on the continental railways (whose length exceeds threefold that of the whole British system), and will have to run distances five times as great as from London to the Highlands.

"The English railway companies, who are now able to follow their rolling stock almost with the naked eye, who know exactly how long each truck will take to run the short distances in their island, who can, therefore, provide proper loads both for the up and down journeys, hence making the best use of their stock, and who are always aware in whose hands their trucks are, will suddenly see a great number of them disappear out of their sight and beyond their control on long journeys and unknown routes."—*Galaxy*.

A CORRESPONDENT, for whose opinion we have great respect, takes exception to a remark of ours in an article in the NEWS of Dec. 23, p. 387, on Continuous Girders, that "It was necessary to use the single intersection system for the continuous girder, as, with double intersection, the distribution of the shear between the two ties which run on each side to the top of the pier post is indeterminate."

While agreeing with us that there is a certain indefiniteness as to the distribution of the shear in the latter case, he thinks that the same difficulty exists in the case of the single span girder; that the small indeterminateness is practically of no consequence in either case; and that it is not fair to single out the continuous girder for a defect which is common to both. We are ready to allow that the indeterminateness as to the distribution on the web members is so small as to be of little or no consequence practically, but we are, with our present light, unable to see why the stress on each of the two ties which come together at the pier post of a single span truss is not definite in amount, unless the two systems which make up the double intersections cannot be separated in the analysis, by reason of the counter ties of one system being joined to the main system of the other. With two independent systems, as usually designed in the double quadrangular truss, a weight at any panel joint has but one plain path to travel to each abutment, and hence we know over which tie in the first panel each portion of the abutment reaction comes.

In the continuous girder, a load on one span affects other spans, the reactions at other piers besides those nearest the loads are changed, therefore the shears are changed and, as the amount of vertical force transmitted across an unloaded span has two paths open to it over two sets of ties, we have seen no reason for deciding that it must go over one path rather than the other. But, as we stated just now, the question is of but little importance.

MEMORANDUM CONCERNING BLASTING OF ICE IN THE WINTER OF 1875.*

During the winter of 1874–5, the ice formed to an extraordinary thickness in all the streams of the west. Towards spring apprehension was quite widely felt that if there should fall a warm rain for two or three days, the rivers would rapidly rise and carry out the heavy ice, sweeping bridges and all other obstructions before them.

The most exposed structure on the Illinois Central Railroad, was the bridge over the Kankakeé river, a Bollman iron truss, of three spans 170 feet each, and two 60 feet spans. About one hundred feet below the bridge is a dam, and during the winter the water stood about three feet below the top of this.

It was thought desirable to break up the ice above the bridge as soon as the water should rise sufficiently to flow over the dam, so that it might pass between the piers in small masses without danger of gorging.

On the 22d of February there were indications of a thaw, and a gang of men with ice tools were put at work cutting the ice near the bridge into cakes fifteen feet square. Preparations were made also for blasting the ice with gunpowder. Two experimental blasts were made, using in each case a six-pound can of rifle powder. A waterproof fuse sixteen feet long was inserted and carefully packed with putty, the can was securely fastened to the end of a two by four scantling twelve feet long, and the fuse attached by twine to the scantling. A hole of sufficient size to allow the can and attachment to be put through was cut in the ice and the can was pushed under twelve feet beyond the hole, being kept against the ice by the float.

The result of each explosion was to break into small pieces a portion of the ice field about fifteen feet in diameter, and to visibly crack the ice, below its surface in several places, for a distance of some twenty feet beyond the broken center. A number of pieces were thrown fifty feet or more into the air. The ice was twenty-six inches thick.

These results gave confidence in our ability to effect a rapid disentegration of the ice. Further experiment was desirable, however, to determine the proper quantity of powder to be used in each charge to secure the greatest execution.

A number of ordinary one-quart oyster cans were procured, and next day several more blasts were discharged. These cans when filled held, each, one pound and three quarters of F F Fg sporting powder, and this charge gave the best results, breaking up the ice for a space about thirty feet in diameter, and throwing out cracks for thirty or forty feet more. The greatest execution was done when the blasts were exploded at a considerable distance from the places previously blasted out, that is, in the unbroken ice field. A charge of one pound of powder did not fracture the ice. A 6¼ lb. can of Dupont's sporting powder opened a hole 30 ft. in diameter and threw many pieces of ice, several feet square, perpendicularly into the air, probably to a height of 150 feet, the fragments falling within a radius of 100 feet. The seams in the ice, however, were not opened to any greater distance than in the 1¾ lb. charge. Ordinary blasting powder was tried, but it did not break through the ice. A charge of nineteen lbs. had the effect to raise the whole mass of ice extending across the river several inches, but without producing a fracture. A similar charge exploded six feet below the surface had no immediate perceptible effect.

After the explosion of these charges, however, the ice for a distance of five or six hundred feet up the river appeared to be seamed with cracks and ready to go to pieces.

I had been told by a gentleman who had tried to blast ice, that it could not be done, that the powder would not break a hole through the ice. Our experience would indicate that his failure arose from the use of ordinary blasting powder, which does not explode with sufficient rapidity.

The cans used with the 1¾ lb. charges were ordinary oyster cans, the round cover being cut in the center with a +, and this punched through from the inside. The four projecting points encircling the fuse being turned back a little seemed to retain the putty packing in place.

The thaw continued during three days and the river continued to rise, though slowly.

Before the rise was sufficient to move the ice, the weather grew colder, and the river did not break up till more than a month later. During the intervening time the ice was much weakened by the sun and by the gradual draining of surface water into the river. Little apprehension was felt at last, but the precaution was taken to plow the ice with ice plows, for a considerable distance above the bridge, so that it would break up into cakes of a diamond shape, about one hundred feet in length.

On the 28th of March, the water was four feet deep over the dam, and the ice went out. For the most part it broke into the cakes as plowed, but several times during the day there was a disposition to gorge at the bridge. One or two blasts with one and three quarter pound charges, however, had the effect each time to break up the ice so as to keep it in motion. No injury was done to the bridge or to the piers. The ice was about eighteen inches thick when the river broke up.

*Paper read before the Civil Engineers' Club of the Northwest, Jan. 2d, 1877.

Extract from a letter addressed to the Secretary of the Civil Engineers' Club of the Northwest, by Col. F. U. Farquhar, U. S. Engineers. St. Paul, Minn.

* * * * In March 1875 we found that our turbine wheel was not doing as well as it ought to, and on examination the cause was found in the immense thickness of the ice, which in some places was frozen to the bottom, and leaving only a very small channel for the water to reach the turbine. The extreme thickness of the ice was no doubt produced by the freezing of layers of water on top of ice already formed. It was decided to cut a channel through the ice from the foot of the mill-pond to the open water in the river above. A hole was cut through the ice and it was found to be five feet (5′) thick. After a little work by hand, the tools being axes, picks and pike poles, it was determined to try the effect of dynamite, as we had a small amount on hand. The result was very successful. A ½-pound cartridge was fastened to a pole about 10 feet long. A Brown's exploder had been inserted in the cartridge and the wires from it carried along the stick. The cartridge was pushed up under the ice as far as the stick would allow. The end of the stick was made fast to the ice at the opening and the wires carried to a safe place and connected with the poles of a friction battery. The battery was charged and the cartridge fired. The result was that, while no hole was blown through the ice, it was broken up so as to be easily removed with pike-poles for a space of about 10 to 12 feet in diameter.

* * * The Minneapolis Boom Co. used the same means to open a channel and start the ice from above the dams before the rise of the river. For thinner ice a slower burning explosive would be better than dynamite. I have not the means at hand to give the cost, etc., of doing the work but only know that it was a very rapid way of getting it done. * * * * *

SURVEYOR MONOPOLY.

To the Men of the Profession of Surveying:

Being known as a certain fact to the writer of this article, that a certain newly elected State Senator of one of the lower districts of this State and particularly influenced by an ignoramus of a lately elected County Surveyor, totally unqualified for the fulfillment of his duties, is about ready to introduce as his first act a bill to the effect "that none but a duly (by the voice of the people) elected Surveyor, whether qualified or not, shall be permitted to execute any survey or county engineer-

ing work within the limits of the county; neither placing him under bond or requiring any qualification."

The present surveyor law as in force in our State (Cook County excepted) in which county licensed surveyors have the same power as county surveyors, gives some power to the non-county surveyor, that is, it does not exclude him from executing any work, but in most cases, through the ignorance of the farming population, most of the work, and all of the county work goes in the hands of the county surveyor, hardly ever considering his ability.

Under the present law, and as it has been the case in our county (in which a very experienced surveyor is wanted to operate) men, entirely unknown and unfit for the office, men who had no idea of the use of a common compass, or who never studied the first rudiments of geometry and algebra, and had hardly a common school education—by political trickery are elected to the office, and are afterwards the cause of many troublesome lawsuits. In order to keep the professional surveyors from executing any work the surveyors' records are sometimes destroyed or taken away to a place unknown to them, and by these means forcing the people to employ the county surveyor. In the county where I reside a great amount of *crooked* surveying is done, and has been done by the county surveyor, and the intelligent land owners try to seek relief by praying the intelligent surveyors and engineers of this State to co-operate and do something so that the professional surveyor will have a chance to execute surveys legally.

Fellow Surveyors! Let us unite as soon as possible in Springfield, on some day during this month, if possible on the 15th or 22nd, to discuss the present condition of our surveyor's laws and see what can be done in order to improve them. Let us use our influence towards inducing the present Legislature to do away with our present surveyor law and follow in progress the surveyor's laws in force in the city of Chicago.

CHAS. A. M. SCHLIERHOLZ, C. E.

MONROE Co., Illinois.

The present law of the State of Illinois requires only that a surveyor shall be "competent" in order to allow him to make surveys and subdivisions in any part of the State, including Cook Co. and the city of Chicago. What is desirable now is to *prevent* any further legislation, and concentrate any efforts for improvement in abolishing the *name* and *office* of *County* Surveyor, for, as the writer of the above appeal states, ignorant people imagine that the county surveyor is the only person authorized to make legal surveys, whereas he has no such privilege.—[ED.]

COAL GAS.*

BY WM. D. MARKS.

(*Concluded from page 10.*)

Four hours is the usual time that a charge is allowed to remain in the retort before being drawn. Five, and even six hours, occasionally is the time for which a charge is left in a retort, but after four hours the gas is of very low illuminating power and distilled in small quantities and not worth the fuel.

It is of paramount importance to keep the pressure in the retort, equal to that of the atmosphere outside or even a little less, and the heat of the retorts high, an orange yellow being considered the best temperature for clay, at which high heat it is considered that less tar and more gas is obtained from coal than at the lower temperature formerly used when iron retorts made them necessary.

The pressure is regulated by means of an exhauster, which rapidly withdraws the gas from the retorts when made, and prevents their incrustation by the carbon derived from the illuminants, which it is the first object of the engineer to secure.

The first of the purifying apparatus into which the gas enters is the condenser, where it is cooled to the temperature of the atmosphere, and where also it deposits most of its tar and oily hydrocarbons which have been brought over in vapor. On entering the scrubber which follows the condenser—the gas parts with its tar and a portion of its gaseous impurities,—carbonic acid, sulphuretted hydrogen and amonia—the amount of which is uncertain. Foule's experiments at Breslau in 1860 would indicate that in every 1000 volumes of gas there is detained in the scrubber 6 volumes of carbonic acid, 10 volumes of sulphuretted hydrogen and 10 volumes of amonia.

The lime purifiers, which are the last of the purifying apparatus, take up the remainder of the carbonic acid and sulphuretted hydrogen in the proportion of about 30 volumes of the former to 5 volumes of the latter.

Thus—neglecting the small quantities of the illuminating gases which are mechanically arrested in the apparatus—we have left of the original 1000 volumes of gas, 930 volumes which latter is increased by air unintentionally introduced during the progress of the gas through the apparatus.

The gas is now measured by the Station Meter and goes to the gas holders where it awaits distribution.

In the matter of distribution, which is an important one, there are several points to be noted. Great pains must be taken to secure a perfect pipe system so that every district shall have an abundant supply. The consumers must have all the gas they want. It is a very common but poor policy to have pipe so small that consumers cannot get all the light they wish at the very time they most desire it. As gas is coming into use for heating and cooking purposes, that of abour 14 candle power will be found to be the most economical for consumers, when used for illuminating purposes also.

Gas companies ought to encourage a large day consumption.

In constructing works it is best to put them up as conveniently and handsomely as possible, as it raises the standard of the officers, prevents a lot of shanties from growing up around the works, and does not lower the value of surrounding property.

I can perhaps do no better than close this paper by a short description of the Laclede Gas Works as now erected in this city, (St. Louis).

February 2nd, 1872, the company purchased about five and one-half acres of ground situated at the foot of Howard street and between Main street and the Mississippi river.

The limestone formation at this point either crops out at the surface, or at the most—with the exception of a filled up quarry—is but a few feet below, thus affording a perfect foundation for all such buildings as are erected, but adding to the expense of the connections in the yard, which have to be laid in trenches blasted from the solid rock.

The North Missouri railroad has a right of way thirty feet wide through the ground, and the Transfer Co. has its ferry landing at the foot of Mullanphy street immediately south and adjoining it.

The water front on the river is about 439 feet in length, so the company had ample facilities for the delivery, either by rail or water, of all coal needed.

The Retort House is built entirely of stone and brick laid in cement mortar, and iron, and is from the designs of Wm Farmer, Engineer, of New York City.

This building has a front of 119 feet and a depth of 103½ feet. The height from the bottom of coke cellar to the eaves of the roof is 38 feet.

The outside walls of the coke cellar are built of coursed rubble two feet thick and reinforced at the front and rear of building by counter forts 36 by 24 inches at the base placed 18 feet 6 inches apart.

To this cellar at the ordinary level of the ground are sixteen arched entrances for wagons, ten feet wide and twelve feet high.

In the interior are two lines of brick arches upon stone piers, which support the benches; these benches which are at the level of the firing floor are in sets of five, and there are at present one hundred retorts set, which will have a maximum of 600,000 cubit feet. During the ensuing summer a second stack of benches of equal capacity will be built.

The firing floor is made of cast iron plates riveted down to wrought iron girders and immediately under each mouthpiece is a wrought iron trap-door to allow the coke to fall into the cellar when the retorts are drawn; this floor will be reached by means of 2 hydraulic lifts of 16 feet lift, the coal being brought into the Retort House in dumping barrows.

The roof to this building is made double, with a valley gutter and 24 trusses, each constructed with 12 principal trusses placed 7 feet 10 inches apart from center to center having a span of 59 feet.

Angle iron purlins are placed 8 inches apart between the principals, and the slate is fastened to these by lead nails.

Following the 29-inch main which takes the gas from the Retort House, we next come to the building in which the gas is purified and measured, and in which, contrary to former custom, all the apparatus are placed in the most compact form.

This building is 132 feet deep, and has a front of 64 feet 6 inches; it faces, and is on Main Street, the offices of the engineer and book-keeper being to the right and left of the front entrance while the station meter occupies the vestibule, which is tiled with marble and paneled with black walnut, and presents a strikingly elegant appearance: above the offices are two rooms which will be used for drawing, meetings of the officers of the company and such similar purposes.

The gas on entering this building first passes through the Multitubular Condenser, a cast-iron tank with a base 5 feet 10 inches by 21 feet 8 inches and 15 feet high; this tank contains 400 3-inch pipes, 11 feet 7¼ inches long, through which the gas is obliged to pass, and these pipes are arranged in four stacks of one hundred each and cooled by water, which is constantly passing through the tank.

The Liversy Scubber to which the gas next comes is a square cast-iron box 6 feet 8 inches by 6 feet 8 inches external dimensions and 24 feet high. In the interior of this box are placed on edge and very close together, slats six inches wide by one-fourth inch thick. Water is allowed to drip from the top while the gas comes from the bottom.

The horizontal engine used to drive the Root's exhauster is of twelve-horse power. In the same room with the engine and exhauster are placed a Lowe's Jet Photometer and pressure and vacuum gauges, which two last communicate with the outlet of the exhauster and directly with the Hydraulic Main, so that the engineer will always have the power to so regulate the exhauster as to keep the gas within ½ candle of any fixed standard of illuminating power.

From the exhauster the gas goes to the dry centre seal and through the purifying boxes; these boxes are twenty feet square and contain seven tiers of rattan lime trays, each box holding about seven tons of slackened lime.

The case of the Station Meter used is eleven feet internal diameter, and an eight-day clock with tell-tale movement is placed over the index.

The tanks for Gas Holders are ninety-seven feet in internal diameter——inches thick at bottom and diminished to 24 inches at the top which is covered by limestone coping. Their depth is twenty-five feet six inches, and the bottom, which is solid rock, is covered first with clay puddle and then with concrete in two coats, each six inches thick. All brick are laid in cement mortar, one-third cement to two-thirds sand, and each course grouted with liquid cement, the outside of tank walls having a coating of one-fourth of an inch thick, and being filled in with clay puddle around the whole outside.

The two gas holders are telescopic and built with a flat top without trussing.

The inner or upper sections are ninety-four feet in diameter and twenty-five feet deep; it is fitted with a grip or reversed cup at its upper edge which grasps the hydraulic cup when it has risen to its full height.

The columns for each holder are eight in number, fifty feet in height and——inches in diameter at base, and in the interior of each are placed the counter weights for the lower lift of gas holder and they are connected at the top by lattice girders three feet deep.

Each of the holders when at its full extension will contain 350,000 cubic feet of gas.

*A Paper read before the Engineers Club of St. Louis, April 30th, 1873.

CORRESPONDENCE.

TORONTO, *January 4th*, 1877.

Editor ENGINEERING NEWS:

SIR:—Application will be made at the next session of the Parliament of the Domin on for Power to construct a bridge across the St. Lawrence at or near Quebec, for the passage of railway trains and ordinary vehicles.

A meeting of architects took place here on the 28th ult. for the purpose of organizing an Architects Association for the Province of Ontario. After electing Mr. T. J. Rastrick, President; Mr. Langley, vice President; Mr. Smith Treasurer, and Mr. Frank Darling, Secretary, a Committee was appointed to draft a constitution and by-laws. The Association then adjourned to meet again soon at the call of the secretary.

The town of Guelph is to have a street railway connecting the passenger stations of the Grand Trunk, and Great Western Railways, which are situate on opposite sides of the town.

In order to ascertain as correctly as possible the condition and extent of the Oil production of Ontario, a London paper recently sent a special and well qualified reporter to Petrolia, where he spent several days in collecting information. From his long and interesting report just published, I glean the following:—There are 308 pumping wells in the Canadian oil regions with a

daily production of 1179 barrels. In addition there are 43 drilling and preparing to drill, and 17 preparing to "start up." The total consumption of crude oil in Canada is fully 70,000 barrels a month; at present the yeild does not equal the consumption. The stock on hand at Petrolia is about 175,000 barrels. The average cost of simply drilling a well, is fixed at $175. With machinery and general appliances, the cost is about $1.300.

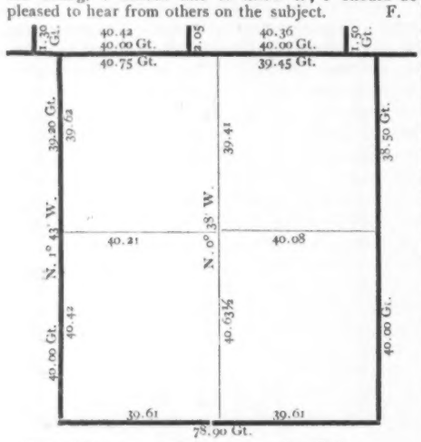
Several deaths having recently occurred at our railway stations through pedestrians getting their feet caught in the 'frogs," it is suggested that Parliament should make railway companies liable for heavy damages in all such cases; and also, if possible, force the companies to employ some less dangerous creature than the *frog* aforesaid, to secure the crossings of their tracks. Should not legislation go a little further and provide for the punishment of people who will insist upon walking over such parts of railway tracks,—particularly at and near stations—as are intended for the accommodation of trains only? A large proportion of the 'accidents" we hear of result from the carelessness or temerity of the unfortunate victims.

The track of the Hamilton & Northwestern railway is now laid to within a mile or two of Stewarttown, and the company are now advertising for ties for the line between Georgetown and Barrie. CANADENSIS.

CARTHAGE, ILL. *Jan. 4th*, 1877.

Edit r ENGINEERING NEWS:

SIR:—In your issue of Dec. 23rd in the communication from the Land Commissioner, he alludes to the vexed Question of due north. I send you a diagram of a section which is a case in my practice, and desire to call attention to the ¼ section corner on the north side. The Original field notes of the government surveys in this region, show that the North and South center lines of the north tier of sections, should be parallel with the East line of the section and the areas are calculated accordingly; now shall I calculate from the data given me in the original note the distance between the ¼ section corner made for the section north and the corner in Question; or shall I first measure the lines and then adopt a proportional measurement, as stated by the commissioners. My plan has been to set this corner by calculation, but I am not aware to what extent it is done by others. When there is no opposite corresponding ¼ section corner I would run parallel with the east line, and in this case I regard the corner placed by calculations as the true opposite corresponding corner. If I am wrong, I should like to know it; I should be pleased to hear from others on the subject. F.



[We will give our opinion next week.—ED].

BOSTON, *January 1st*, 1877.

Editor ENGINEERING NEWS.

SIR:—Mr. Tubbs can find the information he desires in "The Brooklyn Water Works and Sewers" Van Nostrand, 1867, pp. 78–81. The fomulæ as given there are:

$$D = \left\{ \frac{m^2}{1450\,S} \right\}^{\frac{1}{5}} \quad \text{and} \quad D = \left\{ \frac{m^2}{1450\,S} \right\}^{\frac{1}{6}}$$

in which

M = disch. in cub. feet per second.

S = sine of inclination, or $\frac{H}{L}$.

I transposed and changed the form somewhat. Mr. Kirkwood makes this modification in order to approximate to the experimental results obtained by Roe. He thinks the increased discharge of sewers, above that given by old formulæ, is due to the sharp inclinations of house drains, gully pipes etc., which discharge into the sewers at great velocities; a condition which doubtless does obtain in times of storm, and in settled districts.

I send herewith two diagrams,* showing the relation of Diameters to Acreage, by three characteristic formulæ; each of which is used in practice. Prony, Eytelwein, Darcy and the other old authorit es do not vary much from Weisbach. Mr. Shedd, at Providence, uses a rule almost identical with Kirkwood's.

It may interest your readers who have not looked into the matter, to note the divergence of these formulæ.

ELIOT C. CLARKE.

* These diagrams will be published in a future issue.

SANTA FE, NEW MEX., *Dec. 30th*, 1876.

Editor ENGINEERING NEWS:

SIR: In your paper of the 9th and 23rd ult., your correspondents have revived the witch Hazel subject. (I think it would be impossible to put a well down anywhere in Eastern Massachusetts to a reasonable depth and not find water.)

During the years 1865–66 in the oil regions of Pennsylvania, parties extorted considerable money from confiding individuals, making them believe the witch Hazel had a certain property in the hands of parties of sufficient magnetism to indicate the presence of oil, water, or other valuable products.

I knew many wells to be located by this means, some by parties who secretly believed in it, and yet ashamed to acknowledge that they did so. I myself experimented with the twigs to my entire satisfaction. I will wager that I can take the forked sticks hazel or any other wood suitable to the purpose, hold one end in each hand, the crotch or fork pointing up, then I will walk about and have the point turn over, when passing a given point, and a looker on shall not see the least change or movement in my hand or arm, and when I leave the place it will rise again without any apparent effort. I will then show that the twigs have been held very firmly—somtimes the bark rubbed off in my hands, and apparently considerable force exerted—very likely five out of ten men would believe in it. Vet the hazel turns by my will. I know that it is done by the most impercepurable movement, scarcely noticeable to myself. There are several opposing forces to work. I am not quite certain that Duchaley's method of solving opposing forces would solve this or not. Col. Olcott who has so thoroughly investigated spiritualism, might be induced to look into this, he might not come to conclusions as quickly as some others, but he might make it entertaining, besides assisting to dispel a popular superstition from the enlightened people of New England, which, had it been entertained one hundred and eighty years ago, might have led one to Salem's hill.

"APACHE."

FORT WAYNE, IND., *Jan. 4th*. 1877.

Editor ENGINEERING NEWS:

SIR:—Being a new subscriber, I am unacquainted with correspondence upon sewerage referred to by your correspondent G. M. A. in No. 53, Vol. III. An overworked city engineer is also too busy with the affairs of his office to enter upon correspondence of this nature I, however feel like dropping a line upon this particular matter, and if you deem it of interest you can publish the communication. The fact that the coefficient of friction, C *f*, is found to increase as the velocity decreases, will account in some measure for slight differences in formulæ. C *f*, for a velocity of 1.5 ft. per sec., is .0069914. whence $v = 96\sqrt{rs}$; for *v* of 2 and 2½ it is .0064403. whence $v = 100\sqrt{rs}$; for 20 ft. it is .004556, from which $v = 118.3\sqrt{rs}$. From 30 experiments on canals, where the velocities did not exceed 3 ft. per second, Prony deduced $v = 103\sqrt{rs} - .24$ nearly. For pipes Prony found from 50 experiments made by Du Buat, Bossuet and Couplet, with pipes from 1 to 5 inches diameter, and from 30 to 00 feet long, and one pipe 19 inches diameter and nearly 4000 feet long, $v = 97\sqrt{rs} - .08$ nearly. Prony also makes the following formulæ appl cable to pipes or rivers $100\sqrt{rs} - .15$ nearly. Eytelwein, from experiments on rivers gives $v = 93.4\sqrt{rs}$, and for pipes $v = 108\sqrt{rs} - .13$. D. Aubuisson, from an examination of the results obtained by Prony and Eytelwein, assumes for pipes $v = 98\sqrt{rs} - .1$ nearly. For rivers he assumes $94.5\sqrt{rs} - .11$ nearly. When the velocity exceeds 2 feet per second, he assumes $v = 95.6\sqrt{rs}$. Values found best to agree with the general run of experiments in clear, straight rivers of uniform section is $v = 93\sqrt{rs} - .02$, which, for average velocities of 1½ feet per second, will give $v = 92.3\sqrt{rs}$, and for larger velocities, $93.3\sqrt{rs}$. Mr. Neville's valuable formula, $v = 140(rs)^{\frac{1}{2}} - 11(rs)^{\frac{1}{4}}$, for velocities of 2 feet gives $v = 100.3\sqrt{rs}$, and for velocities from 1 to 20 feet the formulæ varies from $v = 93\sqrt{rs}$ to $v = 120\sqrt{rs}$. The Brooklyn formulæ, $v = 48.5\sqrt{DS}$, or for discharge $m = 38.08\,D^2\sqrt{DS}$, or diameter, $D = \left\{ \frac{m^2}{1150} \right\}^{\frac{1}{5}}$ is reducible to $97\sqrt{DS}$. Eytelwein's formula, quoted by Latham, $v = 93.4\sqrt{rs}$, is reducible to $m = 36.67818\,D^2\sqrt{DS}$.

say $36.68\,D^2\sqrt{DS}$, whence $D = \left\{ \frac{m^2}{1345\,S} \right\}^{\frac{1}{5}}$.

The Brooklyn formula, for acres, with one inch of rainfall, half an inch reaching the sewer in the same time

$$D = \left\{ \frac{m^2}{5804} \right\}^{\frac{1}{5}}$$

Eytelwein's would be, $D = \left\{ \frac{m^2}{5330\,S} \right\}^{\frac{1}{5}}$

Mr. Roes, - - $D = \left\{ \frac{m^2}{5806\,S} \right\}^{\frac{1}{6.4}}$

This is, of course, upon supposition that but half an inch reaches the sewer in an hour. If we supposed that the whole amount, or one inch, reached the sewer in that time, the Brooklyn formula would become $D = \left\{ \frac{m^2}{23216\,S} \right\}^{\frac{1}{5}}$ and Eytelwein, $D = \left\{ \frac{m^2}{21520\,S} \right\}^{\frac{1}{5}}$

and I suppose it is under this latter condition of the formula that G. M. A. figures 37 acres. It will be observed that all the formulæ I have quoted differ only by a small percentage, and as the discharge of circular sewers and pipes are as the 2½ powers of the diameters, a difference in the diameter which in practice amounts to nothing, overcomes this percentage and places the sewer, as regards capacity, on the side of safety.

In my own practice I figure the size according to the different authorities and in the "evening up" can always keep on the safe side. I quite agree with G. M. A. that some of the practice in the western cities would l ad to the supposition that the formula quoted would give insufficient provision for sewerage discharge. I am, however, also satisfied that there is abundant room for improvement in the western practice. and that such improvement would save corporations immense sums of money. I am now engaged at a plan of sewerage for this city, and would be much interested in anything our hydraulic engineers may be pleased to publish upon the subject.

JOHN RYALL, *City Civil Eng'r.*

PAW PAW GROVE, ILL., *Jan.* 8, 1877.

Editor ENGINEERING NEWS.

SIR.—Enclosed please find post-office order for $3.00 for which please send me your paper for another year. Although I am only a land surveyor I cannot think of giving up the ENGINEERING NEWS. In your "Special for Land Surveyors" you seem to think that if we only have a Gurley compass and chain and a few other cheap instruments (I suppose you mean by that an old brass semicircle and boxwood scale with an old pair dividers made of brass and iron), we want nothing else.

This description would be all a land surveyor could afford if kept up by the pay received f r his work, but, so far as I am acquainted, your "Special for Land Surveyors" is entirely overdrawn. I don't know a surveyor of any respectability in this part of the country that uses Gurley's cheap instruments. I have always used Young's and now am using a Young's Transit. The surveyors of De Kalb and LaSalle I know use transits of the best makers, and know how to use them.

I am aware that many surveyors are unworthy of the name and are not acquainted with the first principles of surveying, but we are trying to improve on that grade of surveyors—and we want you to help us all you can. You have given us a great deal of standard information the last year, The knowledge that could be acquired through the columns of your paper is invaluable to the land surveyor, and is just as valuable to railroad engineers, as they, in locating lines of railway, must connect their lines with the government survey, and should also understand thoroughly the mode of dividing sections.

I have perused your paper carefully from the first number to the last, and must say that your decisions in regard to land surveying and especially the divisions of sections are to the point, and if followed closely would keep many a land holder out of the law's clutches. Although running section lines and dividing them up properly is, as you say, a very simple process, yet there are many that practice surveying, and among them engineers of some eminence, one of whom I am well acquainted with, a chief engineer of one of the leading railroads in this state, who divided the N W¼ section 30, the same as he would have done any other section, and had his division line about 4 rods out of the way. Knowledge is what we all want and we want to get it out of ENGINEERING NEWS. Give us something in almost every number, if it is but a line, and you will soon have all the intelligent surveyors supporting your paper, and it makes but little difference where the rest are found. WM. MCMAHAN.

County Surveyor.

THE STEEL RAIL INDUSTRY OF CHICAGO.

We extract the following interesting review of the steel rail industry from *The Chicago Times*, of the 24th ult.

Chicago is now the centre of a considerable rolling-mill interest. Four mills, among the largest in the country, are hereabouts. One of them is even something of a monster, employing as it does when full-handed, a brigade of 1,500 men. At least two of these mills are now almost exclusively—one of them is entirely—devoted to the manufacture of steel rails, and one-fourth of all the material in that line manufactured in the whole country is turned out here. Formerly these mills devoted themselves exclusively to iron products, but now the old order is almost completely reversed. The iron rail is now virtually out of date, and is being replaced by steel almost as fast as the article can be manufactured. The revolution in this respect is in fact so complete that no first-class road could afford to put down iron hereafter, though the material were given to it. The price of steel rails per ton at present is about $55, and of iron about $40. How much longer a steel rail will last than an iron one it is hard to say, for the experi-

ment is not old enough to present reliable data. Some maintain that a steel rail will outwear four iron rails, some that it is as good as eight, others that it is equal to 12, and so on upward, until one need not be surprised to hear men say that a steel rail will never wear out. At the "Centennial" a steel rail was exhibited from Cleveland that had worn out 21 iron rails, and was still in excellent condition. The test was begun many years ago. This steel rail was laid down at a point in the track where it was almost uninterruptedly in use, and opposite to it was placed an iron rail. Now the claim is that the competing iron rail has been replaced 21 times. The Chicago, Burlington and Quincy road reports even a better case. Some steel rails in use in one of their yards have served equal to the durability of 32 iron rails, and are still almost as good as new. On the part of the manufacturers, the rail is guaranteed for five years. When it is demonstrated that a steel rail will outwear at least half a dozen iron rails, it is easily understood why it would not pay a first-class railroad to accept iron rails as a gift. In the first place, the steel rail is much safer,—and the best security is none too good in connection with modern fast time.—and, secondly, the cost of the frequent replacement of the iron rail would soon amount to the full measure of the expense of steel rails. It is only the most slovenly and least-used roads that lay down iron now. In some instances it is, perhaps, quite as good as it needs be. In the case of roads that run only one or two trains a day, and that at a rate that admits of passengers, playing a game of ball by the wayside, iron rails will do very well for 20 or more years. But so would wooden ones.

The manufacture of steel rails in this country used to afford an immense profit. At one time they were as high as $150 per ton, and even as late as 1871 they rated at $125 per ton. Since that time, however, they have been subject to a steady decline,—a sort of galloping consumption, in fact,—until now the price is down to $55, or but a trifle over one-third of the figure that ruled but a matter of six or seven years ago. When this high figure obtained, the manufacture of steel rails was still in its infancy in this country, and nearly the entire supply came across the water from England paying a high duty at the port of entry. As soon as the home manufacture commenced in earnest,—Chicago being among the first to enter the list—the price began to decline, partly owing to competion, but mostly to hard times that immediately thereafter set in. English competition is now virtually ruled out of the market, owing to the tariff, and prices are exclusively governed by home competition. Profits are now almost entirely governed by locality. In other words, this business now is run on such close margins that the question of transportation is the deciding factor. It is only after our own mills are gorged beyond their capacity that eastern manufacturers can afford to come into this market and compete for the western supply. Otherwise the difference in the cost of transportation effectually keeps them out of the field. This being the case, it will be readily appreciated that the rolling-mill interest of the west enjoys a decided advantage over that of any other section of the country. The main lines in the east are already pretty well supplied with steel rail, and the southern roads are too poor to put down anything, but must hobble along as best they can. Hence it is in the west that the chief demand is made and the question of transportation being the deciding factor, it is quite natural that our mills should carry off the palm. Thus it happens that while the iron interest of the country generally is dull to stagnation, we are doing a lively business, and that, too, at a reasonable, and even encouraging profit, so much so, in fact, that the capacity of our mills is continually increasing.

For the manufacture of steel rails Chicago is peculiarly and most favorably situated. Practically she has nothing within her borders that belongs to or enters into the manufacture of steel save the mills and a superabundance of energy and yet we can manufacture cheaper than any other place in the country. The reason for this is that three things enter into the manufacture of steel, and in no instance are all three of these things found at any one place. Two kinds of iron ore are essential, and coal. When the coal is found the iron is apt to be wanting, and the two kinds of iron that enter into the problem are never found together. Now, it so happens that while Chicago has neither coal nor iron mines in her immediate neighborhood, she sits simply "betwixt and between," and thus enjoys an immense advantage, the more so as the transportation rates from one of the iron regions that serves as a source of supply, Lake Superior, are merely nominal. Under these conditions it is more than probable that Chicago will one day become the great steel manufacturing centre of the country.

GLEANINGS FROM CORRESPONDENCE.

It will give me pleasure when my time will permit, to send an occasional article. It should be impressed upon our American engineers that it is their *duty* not to let their experience die and be "interred with their bones;" let them rather, embalm it through the press.

W. MILNOR ROBERTS.

Allow me to express my appreciation of the great value of your paper; it is rapidly becoming *the* civil engineering journal of the country.

MANSFIELD MERRIMAN.

Since the matter of legislation has begun to be agitated, I think it should be so directed as not to be simply in the interest of men who happen to hold the office of county surveyor, but who are not competent surveyors. Would it not be possible to have some sort of an organization among the surveyors, like the Engineers' Club, or at least something by which the better class of surveyors could know each other?

J. G. F., *County Surveyor.*

[We will have something to say on this subject shortly.—ED.]

I have a complete file from the commencement of your paper, and it makes a collection of facts, principles and decisions which I could not afford to be without for five times the price of the paper, especially as I am a young engineer, and have had limited opportunities for studying the higher branches connected with the profession. So, for my part, I am glad to know you are undertaking to publish some of the standard works, and hope they may prove a financial success to you.

S. D.

PERSONAL.

Mr. Carl O. Wederkinch, who did some very delicate and difficult engineering work in the Hoosac Tunnel with great success, and was subsequently employed on the Sutro Tunnel in Nevada, is now in charge of the Silver Islet silver mines on the Canadian shore of Lake Superior.

Mr. Wm. Wickham Reeve, for over sixty years a civil engineer, died at his residence in Middletown, N. Y. Dec. 25th, aged eighty-four years. He was employed in the first surveys made for the Erie and later located the Middletown, Unionville & Water Gap road, and was Consulting Engineer on the Midland.

NOTES.

All work in Fairmount Park, Philadelphia, has been stopped for want of money.

The coast survey boats are all in snug winter quarters at Seattle, Wash. Ter.

The government authorities are still at work on the jetties for the protection of the beach in front of the light house at Atlantic city.

The Hudson County, N. J., Gas Company have made a reduction in the price of gas from $3 to $2.75 per 1,000 feet, to take effect on January 1st.

The Hell Gate improvement has not as yet been of any benefit to New York shipping. The officers in charge complain of want of funds to complete the works.

The survey of the Calumet river through the village of South Chicago, and the establishment of the dock lines has been entrusted to C. McLennan, C. E., of this city. The price to be paid is $600.

The Common Council of Trenton, N. J., were to take action Jan. 2nd toward changing the grade of several streets of that city. In Chicago that means house-raising and street-filling and paving.

1150 feet of cribbing are now sunk in the Cleveland breakwater at an expense of $58,000. The entire length of cribbing proposed is 7700 ft., at an estimated cost of $1,173,000. Work will be renewed next Spring on further appropriation.

The Officers of the Minneapolis Academy of Sciences for 1877 are: President, R. J. Baldwin; Vice President, S. C. Gale; Rec. Secretary, A. F. Elliot, M. D., Cor. Secretary, P. L. Hatch, M. D.; Treasurer, J. B. Clough. Board of Trustees: Dr. P. L. Hatch. Dr. A. E. Johnson and Dr. A. F. Elliot.

Canada, on the 30th of June, 1875, had 4484 miles of railway in operation, which has now doubtless been increased to 4500 or more. In 1850 the amount was only 51 miles; in 1855 it had jumped to 1218; in the next ten years it was nearly doubled, reaching 2231, and in the next decade to 1875, it had again nearly doubled, rising to 4484 miles—a rate of increase about the same as that of the United States. The number of inhabitants in Canada per railroad mile is about twice as great as in the United States, while the number of square miles of area per railroad mile—153—is nearly four times as great; so that there is a much greater field for railroad operations in the Dominion, if only the extent of territory be considered, than in our republic. Owing to the inhospitable climate of much of Upper Canada, however, those regions will not be fully developed until the temperate zone is peopled.

Now, that a thaw has set in the country roads are in that deplorable condition which winter brings, and locomotion is rendered disagreeable and even dangerous. Deep ruts are the carriage tracks and broken springs are quite the fashion. The man who will rise up and invent a system of road making that will overcome the miserable clay soil and give us firm, hard roads for winter travel, will be a savior of his country, and will be rewarded with a statue, by his grateful countrymen We doubt if such miserable roads exist anywhere else in the Union as in this neighborhood. In New York and Northern Pennsylvania snow usually covers up the ruts all winter, and south of us they do not freeze. But in this section, where it is not cold enough for constant sleighing, and yet cold enough to freeze the mud, we are subject to all the horrors of bad roads.—*Wheeling Intelligencer.*

RAILROAD NEWS.

The Detroit, Lansing & Lake Michigan R. R. has been sold under foreclosure for $15,000.

The Allentown, Pa., Rolling Mill Co. have a large contract for a railroad in Cuba.

The Baldwin Locomotive Works are working 1,039 men, chiefly upon Cuban and South American orders.

Myron W. Bailey, of St. Albans, Vt., has been elected Railroad Commissioner of that State for the ensuing two years.

The Cincinnati, Hamilton & Dayton R. R. has established an office of freight foreman, whose duty it especially is to look after the other brakemen and see to it that his freight arrives safe at its destination.

The latest important engineering work is the Bergen hill tunnel, New Jersey, on the line of the Delaware, Lackawanna & Western R. R. It was begun three years ago, and gave employment to a force of about 600 men. It is nearly a mile long, 27 feet wide, and 18 feet high. Two tracks will be laid through it.

"It is said;" "There is talk;" "It is reported;" "We understand;" "A meeting was held, etc.;" "The people of—Co. are somewhat anxious;" "A company has been organized;" "It is announced;" "Subscriptions are being solicited;" "The road is to be built *if* enough subscriptions to stock are received;" "Work is *to be* begun in;" "If;" etc., etc.. *ad libitum* in the *Railroad Journals.* Pretty weak diet.

The San Francisco *Bulletin* predicts a continuous line of railway from Puget Sound to the Gulf of Mexico within ten years. On to Cape Horn!——Here's "business:" The Tulare *Times* of Dec. 16th says of the Southern Pacific,—"The road west of Goshen is being pushed towards King's river as if by magic. Within twenty days fifty miles will be completed."——Railway building seems to be more active in the far west than elsewhere on the continent. At this season of the year very little can be done anywhere but "project."

The *Railway World* has been raveeing the size but increasing the number, of its pages. It is twenty years old. ——The General Supts. of certain Southwestern railroads have been advising their employes to insure their lives. Prudent!——And still the wages of the "grateful and appreciative" employes are being reduced.——Receiver Grinnell, of the Iowa Central, presented a Christmas turkey to each of his engineers.—29 turkeys. Generous!——There is a "jerk-water" train—whatever that may be—on the Iron Mountain Road.——They are still "signing contracts" to build section 15 of the Canada Pacific R. R. It is about as far as the section will ever get, or ought to get.——President Garrett, of the B. & O. R. R. has been buying pictures.——The "very popular" Superintendents of railways, etc., have been receiving New Year's presents of "plate," etc., from the grateful employes of the roads. Very nice for the Supts.——Mr. A. A. Hobart was recently presented with a $1000 silver service by the C. & N. W. R. R. employes, because he was leaving that road to go to the C. B. & Q. The *Railway Age* is querying what Hobart is going to do with the plate, as he is'nt a married man.——Chairs are scarce on the Gilman, Clinton & Springfield R. R., and so the sympathetic employes have been presenting the Superintendent, Auditor, and Master Mechanic, each with one to rest themselves in. Comfortable!——Occasionally we see a notice in the R. R. papers that another railroad man ventures upon matrimony. Rather reckless.

ARCHES;

CONSIDERED GRAPHICALLY.*

The curved lines of arches are very satisfactory to the eye, and there are many times when it is desirable to introduce them in construction. They may furnish, under some circumstances, a very economical way of spanning an opening, and, in other cases, in conspicuous locations, where beauty of design is regarded, where ample room is desired beneath a roof, and for various reasons, they are employed. Stone arches have been built for many centuries; now-a-days, wood, iron and steel are used as additional materials. If the principles which enable one to ascertain the forces which act in all parts of an arched structure are already understood, designs of this type will be more common.

We are aware how much difficulty most persons experience in first attempting to master these principles, for we can recall the trouble the subject gave us when first entering upon its study. Even one who has successfully worked through the mathematical theory as he finds it in the text-books, may sometimes lose sight of the actual meaning of each step in the process, so that there is a certain mystery about the application of the formulæ to a specific example, although one may feel confident that the results are reliable. To many engineers a treatise on the arch, as usually written, is a sealed book.

It is with the desire to do what we can towards shedding some light upon this subject, as well as to give the ability to design an arch to those who are not familiar with the integral calculus, that we have written these pages. So far as we could, we have obtained our quantities by short and easy ways, and, while it has been convenient to arrive at some of the definite data by the use of the higher mathematics, such data have been obtained from the diagrams, and can be verified by the reader by simple means. It is believed that a number of the facts brought out are new.

An arch may be considered to be any structure which, under the action of vertical forces, exerts horizontal or inclined forces against its supports or abutments. Such a definition would include not only the roof of two simple rafters but also the suspension bridge; and we see no objection to so including them. The case of two rafters we need not touch upon, and the suspension bridge does not come within the scope of these pages, except incidentally, and possibly in the stiffened form, but we do desire to give the principles necessary for investigating stone and iron arches of various forms. We hope to show where certain errors and wrong assumptions have been made by some writers, and we trust that the following investigations will prove of interest and value to all engineers, architects and constructors who may desire to use the arch.

In order that all of our readers may understand the steps taken in the analysis, we have thought it best, at the risk sometimes of appearing to dwell too much on well-known points, to lay down carefully a few fundamental principles, and occasionally, later, to go into some detailed explanations, preferring to err, if at all, on the side of fullness. As we propose, however, to make ultimately, some little use of the method which was elaborated in "Graphical Analysis of Roof Trusses," we shall be obliged to refer to that book, or to Vol. III of "ENGINEERING NEWS," for its full illustration.

It has been our aim to put this subject in such a shape that the reader could follow the reasoning intelligently with only a moderate knowledge of the principles of statics, and if, at times, a section occurs which is not clearly understood by such an one, such portions will prove, we believe, not essential to the understanding of the general subject. It will aid the student greatly, if he will draw for himself, from time to time, the various problems, on a much enlarged scale, care only being required to give accurate results. We need not assure those already familiar with graphical statics how comprehensive and flexible such methods of analysis are, and how valuable they even become as a check on mathematical computations.

1. We know, by one of the first theorems of statics, that, if three forces, not parallel, act upon a body and are balanced, their directions must intersect at a common point, and that these forces must be proportional to the sides of a triangle drawn parallel to their directions; and that, conversely, if three forces be assumed as parallel to

Fig. 1.

the three sides of any triangle, and proportional in magnitude to the same sides, with the direction of the several forces taken in the order obtained by passing over the sides of the triangle in succession, these three forces, applied to a structure so that their directions shall pass through a common point, must balance or be in equilibrium.

Entered accordi g to Act of Congress, in the year 1877, by CHAS. E. GREENE, in the office of the Librarian of Congress, at Washington.

If the weight W, Fig. 1, be hung from two points, A and B, by the cords A C and C B, we may find the pull or tension on each of the cords by drawing a vertical line *a b*, equal, by any convenient scale, to the given weight W, and then drawing the lines *a c* and *b c*, from the extremities of *a b*, parallel to A C and B C, and intersecting at *c*. Then will *a c* and *b c* represent, by the same scale by which W was laid off, the pull on the cords A C and B C. The arrows represent the directions of the stresses relatively to the point C, and the arrows on the triangle *a b c* must be found to point successively in order round the triangle.

If W and the two stresses *a c* and *b c* had been given, we might have reversed the problem, and found the direction and length of two chords which, while supporting W, would have exerted the given tensions on the points A and B. It is well to notice that, as it is possible to draw any number of triangles on the line *a b*, we may have a like number of arrangements of cords from A and B to carry W.

2. If we now refer to Fig. 2, and pay no heed for the present to the curved line, we shall see that, when several weights are suspended from the points A and B, by means of a cord A F B, whose weight may be neglected, the tensions on the several portions of the cord may be found by the successive applications of the above process. Thus the weight at G is balanced by the tensions of B G and G I, and we may draw the triangle of forces for the point G. Next, having the weight W_3, and the tension, just found, on G I, we may draw a triangle for the point I, and so on.

But, since each of the triangles will have one side, which represents the weight, vertical, and since one side is common to every two triangles, they may all be combined in one figure by the following construction. Draw a vertical line 2-1, and measure off on it W_3, W_2, etc., successively, by any convenient scale of pounds or tons to the inch. Draw 1-0 parallel to B G, and 2-0 parallel to A K. Connect the point 0 with the other points of division on the vertical line. Then will 1-0, 3-0, 4-0, and 2-0 be equal to the stresses in B G, G I, I K and K A, and the portions of the cord must be parallel to the lines radiating from 0, or the chord will not be in equilibrium.

3. The figure 012 will be called the *stress diagram*, the vertical line the *load line*, and the cord from A to B, which hangs in what is known as a *funicular polygon*, we shall have occasion to disignate, when it is applied to arches, as the *curve of equilibrium*. When the load is continuous this name will seem more appropriate, but it will also, be used as a general term, even in denoting a funicular polygon of but two lines, like Fig. 1. It will be noticed that

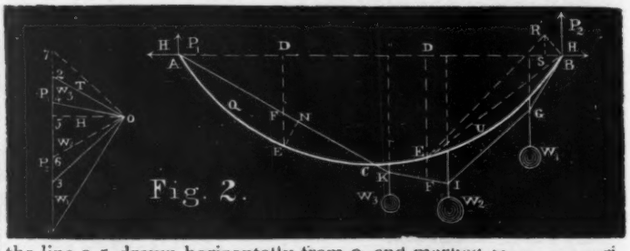


Fig. 2.

the line 0-5, drawn horizontally from 0, and marked H, is the horizontal component of the stress in each portion of the cord, and is constant at all points of a cord under vertical forces or loads only. It will also be seen that we may have any number of funicular polygons between A and B, which shall support the given set of weights at the same distances horizontally from the points of support, the line 1-2 remaining the same, but the point 0 falling at a greater or less distance from the vertical line. H will therefore have a different value for each polygon.

4. Now suppose that a curved rib A C E B, of any material which possesses stiffness, for instance iron, is attached by a pin, on which it can turn freely, to each of the points of support, A, and B, and has suspended from it certain known weights, represented by W_1, W_2, etc., at known points. The weight of the arch itself is not at present considered. The rib, if flexible, as a cord or chain is flexible, will tend to assume the shape of the funicular polygon, or curve of equilibrium, proper to these weights in their respective positions. If we lay off the load line 2-1, to any scale, space off on it the weights in succession, assume any convenient point 0, draw radiating lines from that point to the point of division and to the extremeties of the load line, and then, starting from A, or any other point in the vertical through that point of support, draw lines, successively parallel to the lines radiating from 0, and limited by the verticals through the weights, one such curve of equilibrium will be found.

By moving the point 0 the funicular polygon will strike the vertical drawn through B at a different point, and, if 0 is horizontally opposite the point which divides the load line into the two supporting forces, the polygon, drawn from A as a point of beginning, will strike B. But, even then, 0 may move on a horizontal line, and H will then have any value we please. H is therefore, at present, an unknown quantity; but we will suppose that A E I B is the desired curve of equilibrium for this given case, an imaginary line, the weights being attached to the arch.

RISE AND PROGRESS OF AMERICAN ENGINEERING.*

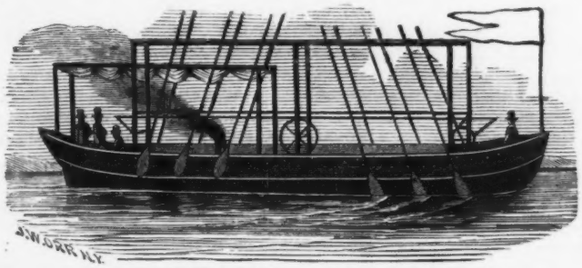
[From the Proceedings of the American Society of Civil Engineers.]

At this Centennial time, when the minds of all are carried back over the past 100 years of unexampled prosperity in the United States, it may not be inappropriate to make a brief retrospect of the progress of engineering in our country since the commencement of its existence, to see what improvement has been made in the profession, and in the size and importance of its works, during the past century.

At the time of the establishment of our present government, very little had been done in the way of public improvement. A few roads had been constructed, such as were suited to the exigencies of the time, and upon them were bridges of rude construction, built as occasion demanded, probably not much unlike the country roads of the present day. They were few and far between, however, and served as the only means of communication from place to place.

Very shortly after the establishment of the general government, the necessity of better means of internal communication became apparent, and considerable attention was given to a better system of roads and canals. Steam, as a means of locomotion was then unknown. Mr. Washington, our first civil engineer, had already given much consideration to the subject of canals, particularly to the connection of Chesapeake Bay with the Ohio river, and made a reconnaissance for that improvement. He also made a report upon an examination of the Ohio river, for which he received the thanks of the Legislature of Virginia.

In 1784, he presided at a commission at Annapolis to consider a project for the improvement of the navigation of the Potomac, which ultimately became a canal to Pittsburg. He was also interested in the Dismal Swamp Canal, connecting Chesapeake Bay with Albemarle Sound. Perhaps the most important work early begun by the general government, was the national road, which extended finally to



THE SECOND EXPERIMENTAL BOAT OF JOHN FITCH.

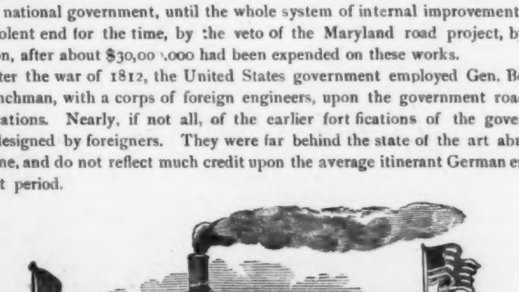
Finished in May, 1797, and run at the rate of four miles per hour on the Delaware. Cylinder 12 inches in diameter, stroke 3 feet.

Cumberland, then through the States of Maryland, Pennsylvania, Virginia, Ohio, Indiana and Illinois, to St. Louis. It was built chiefly by reserving a percentage upon the sales of government land, and was of great value to the States through which it passed, as a means of communication by wagons. A branch turnpike was also constructed from Baltimore to Wheeling. The time of transit from Washington to Wheeling, and from Baltimore to Wheeling, was reduced from eight to three days. Many other roads were projected by Congress, and built under the direction of the War Department.

These national roads were not remarkable pieces of engineering, so far as location and construction were concerned, and involved no extraordinary amount of engineering talent in building them.

Improvements in the navigation of rivers, on a small scale, were also executed by the national government, until the whole system of internal improvements came to a violent end for the time, by the veto of the Maryland road project, by Gen. Jackson, after about $30,000,000 had been expended on these works.

After the war of 1812, the United States government employed Gen. Bernard, a Frenchman, with a corps of foreign engineers, upon the government roads and fortifications. Nearly, if not all, of the earlier fortifications of the government were designed by foreigners. They were far behind the state of the art abroad at the time, and do not reflect much credit upon the average itinerant German engineer of that period.



THE FIRST STEAMBOAT EVER BUILT TO CARRY PASSENGERS.

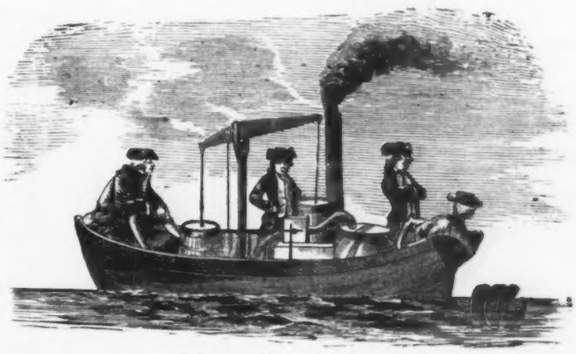
Constructed by John Fitch, and finished April 16th, 1789. Cylinder 18 inches in diameter, speed 8 miles per hour in smooth water. The following year this boat was run to Burlington regularly as a passenger boat.

While the general government was looking after the roads, rivers, harbors and fortifications, the States individually were projecting canals. Pennsylvania, about the year 1788, appointed commissions to examine and report upon routes for connecting the Delaware with the lakes. They reported upon a route by the way of the Juniata, partly by canal, and partly by improving the river. The result was a charter of the Schuylkill & Susquehanna Company, in 1789, and the Delaware & Schuylkill in 1790.

In New York, the Erie Canal had been projected by Governor Morris. In Massachusetts, the Middlesex Canal, from Boston to Lowell, was authorized in 1789, and finished in 1804. In South Carolina, the Santee Canal, 22 miles long, was completed in 1802.

These were but the commencement of the canal systems which were carried out afterwards by several of the States, but the canals already built showed that American engineers were equal to the task that would shortly devolve upon them.

Meanwhile, a slumbering giant, that was to entirely revolutionize the system of transportation, and entirely change the direction of engineering works, was just beginning to awaken to a sense of his power and future ascendancy over the heretofore known methods of locomotion.



THE FIRST PROPELLER EVER BUILT.

Constructed by John Fitch, and experimented with by him on the Collect pond, New York city. The boiler was a 12 gallon pot, with a bit of truck-plank fastened by an iron bar placed transversely. This was in the year 1796.

In 1787, John Fitch, of Connecticut, built, in Philadelphia, the first condensing steam engine in America, with a cylinder of 12 in. in diameter and 3 ft. stroke; and we have every reason to believe that he was at the time ignorant of Watt's experiments in England, which were not made public until 1786. This engine was placed in a steamboat, which was finished in May, 1787, and run at the rate of 4 miles per hour on the Delaware. It was moved by paddles, six on each side of the boat, moving them at one time.

In 1796, the first propeller ever built was constructed by John Fitch, and experimented upon by him on the Collect Pond in New York city.

On April 16th, 1798, he finished the first steamboat ever constructed to carry passengers. The cylinder was 18 inches diameter, and the speed was 8 miles per hour. The following year, 1799, this boat was run regularly on the Delaware river from Philadelphia to Burlington, as a passenger conveyance.

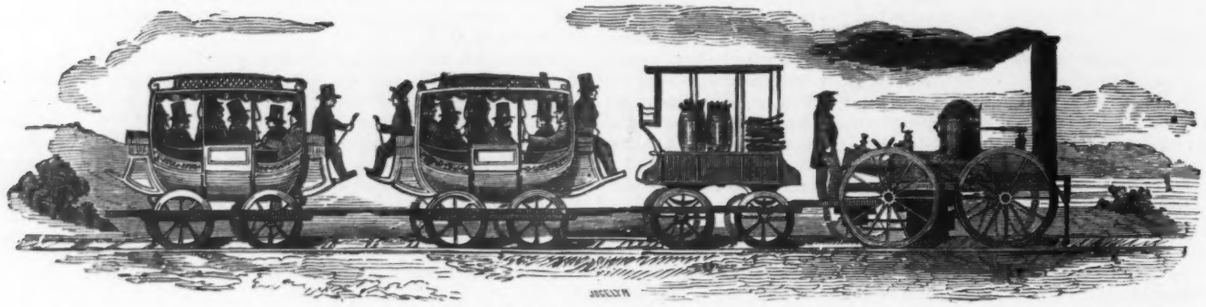
John Fitch saw the value and importance of his invention, and has put it on record in these words: "This will be the mode of crossing the Atlantic in time, whether I shall bring it to perfection or not; steamboats will be preferred to all other conveyances, and they will be particularly useful in the navigation of the Ohio and Mississippi. The day will come when some more potent man will get fame and riches for my invention."

In 1804, Oliver Evans constructed for the Board of Health, Philadelphia, a machine for cleaning docks, which he called the Orukter Amphibolos, or Amphibious Digger. It consisted of a heavy, flat-bottomed boat, 30 ft. long and 12 ft. wide with a chain of buckets to bring up the mud, and hooks to clear away sticks, stones, or other obstacles. It also had wheels for running on the land, and a stern wheel for propulsion when afloat. It was operated by a high-pressure engine, the cylinder of which was 5 in. diameter and 19 in. stroke. The whole apparatus weighed 35,500 pounds, and could be run by the engine up any slope of less than four degrees. This seems to have been the archetype of stern-wheel steamboats, dredging-machines and steam carriages.

Evans was not the original inventor of either the high pressure engine or the stern wheel, but he was the first to apply them to practical use for propulsion. The high pressure engine was invented by Trevithic, in England, and the steam wheel was described by Jonathan Hull, also in England, in 1736. Steam was working its way onward, but at the commencement of the present century it had not yet become a motive power for transportation. Stage coaches, even, had not yet come into general use, and traveling was mainly done by means of the water courses and on horseback. What a field this presented to the American engineer, and how it was improved, we shall see.

Many are still living who might have read in a New York paper, the following advertisement: "*Sloop Experiment.—For Passengers only.*—Elias Bunker informs his friends and the public, that he has commenced running a sloop of about 110 tons burthen, between the cities of Hudson and New York, for the purpose of carrying passengers only. The owners of this vessel being desirous of rendering the passage as short, convenient and agreeable as possible, have not only taken care to furnish her with the best beds, bedding, liquors, provisions, etc., but they have been at very great expense and trouble in procuring materials, and building her on the best construction for sailing, and for the accommodation of ladies and gentlemen travelling on business or pleasure. Merchants and others residing in the northern, eastern or western counties, will find a great convenience in being able to calculate

* Address by Vice-President Theodore G. Ellis at the opening of the Eighth Annual Convention of the American Society of Civil Engineers at Philadelphia, June 13th, 1876.



FIRST LOCOMOTIVE EVER RUN ON THE MOHAWK VALLEY RAILROAD.

(at home) the precise time they can sail from Hudson or New York, without being under the necessity of taking their beds and bedding, and those in New York may so calculate their business as to be certain of comfortable accommodation up the river."

This was luxurious travelling for those days, but Capt. Bunker and his sloop was destined to give way to the power of steam.

In 18 7, Fulton launched the "North River of Clermont," the first steamboat on the Hudson. It was 133 ft. long 18 ft. beam, and 8 ft. deep, and of about 160 tons burthen. She had side wheels of about 15 ft. diameter, with a cylinder of 2 ft. diameter and 4 ft. stroke. The engine was 20 horse-power, of Boulton & Watt's construction, built in England in 1805, which Fulton import d for the purpose. This boat made regular trips from New York to Albany, at a speed of 4 miles per hour.

Robert Fulton, a Pennsylvanian, was a professional civil engineer; he was admitted formally in London in 1795; in 1793 he wrote a treatise upon steam navigation, of great merit at the time. In 1803, Fulton tried some unsuccessful experiments upon the Seine. In 1806, he visited the "Charlotte Dundas," a steam tow boat built by Symington in 1803, and used upon the Forth & Clyde canal, and shortly afterwards returned to New York, prepared to introduce a new era in passenger transportation.

In 1811, Fulton & Livingston built at Pittsburg the first steamboat that ever floated upon the western waters. This was the Orleans, a stern wheel boat, with two masts. In the winter of 1812, she made her first trip from Pittsburg to New Orleans in fourteen days. In 1818, the first steamboat was built for the great lakes, at Black Rock, on the Niagara river. This steamer was named the "Walk-in-the-Water;" she was a fine vessel of 360 tons, brig rigged; with a Boulton & Watt engine, built by Robert McQueen, at the corner of Centre and Duane streets, New York city. Her cylinder was 40 in. diameter and 4 ft. stroke.

Vast strides had been made in the construction of steamboats since Fulton's successful introduction of the "North River of Clermont," and they multiplied rapidly upon all our waters.

Meanwhile, the character of the roads was improving, and internal land communication was becoming of more importance. The stage coach was arriving at its palmy days of transient glory, and engineers were called upon to build more extensive bridges for these rapid transit conveyances to cross the streams. Here was a branch in which American engineering early commenced to show great proficiency. The size of our rivers rendered important and substantial works necessary upon all the main thoroughfares of stage travel. The magnificent timber bridges of Wernwag, over the Schuylkill and at Trenton, were constructed early in the present century, and have been a monument to the fame of the great engineer who constructed them. The celebrated bridge of 340 ft. span over the Schuylkill, was built in 1812, and was burned in 1838. Thus engineering progressed until the great days of railway communication opened a new field for American engineers.

It is amusing now to look back to the period just previous to the introduction of the locomotive engine, and see how the older members of the profession now living, and probably some present, traveled to their conventions, if they had any. At the commencement of the present century, conveyances between New York and Philadelphia were advertised in the Philadelphia papers, as follows:

"*Philadelphia Stage-Waggon and New York Stage-Boat performs* their *stages* twice a week. John Butler with his waggon sets out on Monday from his house, at the sign of the Death of the Fox, in Strawberry Ally, and drives the same day to Trenton Ferry, where Francis Holman meets him, and proceeds on Tuesday to Brunswick, and the passengers and goods being shifted into the waggon of Isaac Fitzrandolph's the same day, when Reuben Fitzrandolph, with a boat well suited, will receive them and take them to New York that night. John Butler returning to Philadelphia on Tuesday, with the passengers and goods delivered to him by Francis Holman, and will again set out for Trenton Ferry on Thursday; and Francis Holman will carry his passengers and goods with the same expedition as above to New York."

Somewhat later an entirely land route was adopted, as set forth in this New York advertisement: "*For Philadelphia and Baltimore—Swiftsure Mail Stage.* A new line has been removed from No. 2 Cortland to No. 116 Broadway, and is now running between New York and Philadelphia, through a beautiful country, on the short and pleasant road through Newark, Springfield, Scotch Plains, Bound Brook, Somerset, Arnwell, Coryell's Ferry, Cross Road Crooket Billet, and Jenkintown to Philadelphia.

"To start from New York every day at 10 o'clock A. M. (Sundays excepted), lodge at Somerset, and arrive at Philadelphia the next day afternoon. The Swiftsure is the only opposition stage from this city to Philadelphia and Baltimore."

A few years more brought steamboats into competition with the mail coaches, and the number of travellers became greater, so that at that semi-centennial jubilee held in Philadelphia on July 4, 1825, it was recorded in the Philadelphia Gazette, that 300 New Yorkers were said to have been in Philadelphia. There were a sufficient number of passengers to fill twenty-five coaches. Fifty years have passed on, and what would Francis Holman, John Butler and Reuben Fitzrandolph, with "his boat well suited," or thirty-five stage coaches have done with the crowd that is here to-day?

The advent of steamboats gave an impetus to engineering works of greater magnitude than before. On July 4th. 1817, the Erie Canal was commenced, and was finished in 1825. In 1819, the first steam-boat that ever crossed the Atlantic, sailed from Savannah to Liverpool. In 1823, the Erie and Lake Champlain Canal, 63 miles long, was finished, and about this time many canals were commenced, some of which were not opened until after railroads had made considerable progress. In 1825, work was commenced on a canal, 307 miles long, to join the Ohio river at Portsmouth, Ohio, with Lake Erie. This was finished in 1833. In 1826, the canal, and afterwards partly railway route, through Pennsylvania was commenced, and this was finished in 1834, 395 miles to Pittsburg. In 1828, the Cumberland route was commenced, and finished in 1840.

Events were progressing rapidly in American engineering about those days; canals and roads had been built, and were building and extending over the country. Steamboats had multiplied, as if by magic, upon all our lakes and rivers, and the excitement regarding internal communications was at its height, when news came across the ocean of the success of the Darlington Railway, which actually carried passengers at the astounding rate of seven miles an hour.

America was ripe for the improvement. A short railroad, the first in the country, had been opened in 1826, from Quincy to Milton, 2 miles, and the next year was continued to Neponset, 3 miles, for the transportation of stone. The celebrated Mauch Chunk Railroad in Pennsylvania, was commenced, and was opened in 1827. Both of these roads were "horse railroads."

In 1828, 12 miles of the Baltimore & Ohio Railroad were completed, being the first passenger road in the country. This was two years before the celebrated Liverpool & Manchester Railway was opened, so that we see that American Engineers were not behind the times. In this same year a survey for a railroad was made in South Carolina, and the Western Railroad in Massachusetts was projected.

The second passenger road opened was from Albany to Schenectady, on the Mohawk and Hudson. This was in 1831. The next road finished in the United States was from Richmond to Chesterfield in Va., in 1831, and the same year the road from New Orleans to Lake Pontchartrain was completed.

The reports from the Liverpool & Manchester Railroad gave a great impetus to railways in America, and they were projected in all parts of the country.

The state of the knowledge of such works at that time may be seen by the following extract from "Wood on Railroads" in 1825: "Nothing can do more harm to the adoption of railroads than the promulgation of such nonsense as that we shall see locomotive engines travelling at the rate of 12 miles an hour."

The first locomotive engine run upon a railroad in the United States was the "Lion," imported in 1829, by Horatio Allen, for the Delaware & Hudson Canal Co. It was first started by Mr. Allen himself, upon the banks of the Lackawaxen, and he has graphically described it in some of his published remarks. This engine was built by Messrs. Foster, Rastrick & Co., of Stourbridge, England. Another engine, built by George Stephenson, is reported to have been imported a short time before the "Lion," exhibited in New York, and run with the wheels raised from the ground. I do not know what road this engine was intended for.

The first engine built in this country was in the summer of 1830, for the South Carolina R. R., by the West Point Foundry Co., at their shop on West street, New York city. It was called the "Best Friend," and had four wheels and an upright boiler. This engine blew up shortly after it commenced running, and was rebuilt with a horizontal boiler. The second locomotive built in the country was the "West Point," likewise for the South Carolina railroad.

In 1831, the "De Witt Clinton" was built by the same company for the Mohawk & Hudson Railroad. This engine weighed four tons, and could run 40 miles an hour. It had cylinders 5½ in. diameter, and 16 in. stroke, with 4 coupled wheels 4½ ft. in diameter.

Concluded next week.

THE ASHTABULA BRIDGE.

With the progress of the coroner's inquest at Ashtabula, some points which bear upon the cause of the disaster come to light. Judging from the reports of the testimony there seems to be no strong evidence that the train was thrown from the track previous to the giving way of the bridge; indeed the impressions of a few of the passengers at the first shock that the wheels were off the rails is naturally the idea that would flash through the brain at such a crisis.

It was previously stated that this bridge was a Howe truss, built in iron, and carrying two tracks on the upper chord; it had a span of about 156 feet, was twenty feet deep between centres, and had twelve panels. It was built about eleven or twelve years ago, to replace a wooden structure of some 300 feet in length, the remaining space, at each end of the truss, being occupied by a stone arch, and an embankment. It contained improvements made and patented by Mr. Amasa Stone, then president of the road, was said to be designed by Mr. Joseph Tomlinson, and was constructed in the company's shops at Cleveland. The responsibility lies, therefore, with the railroad company entirely, if the structure was weak and is shared by no outside firm of bridge builders.

The officials now connected with the road do not testify that they have ever had any suspicions in regard to the strength of this bridge, and they appear to have no theory to offer for the occurrence of the accident. Mr. Geo. M. Reid, the superintendent of bridges for the entire length of the Lake Shore Railroad, testifies that he has been in the employ of the road three years; that previous to that time, he was employed by the McNairy & Claflin Manufacturing company of Cleveland; that he is perfectly familiar with the construction of iron and wooden bridges; that he considered himself perfectly familiar with the Ashtabula bridge, thought it a very strong bridge, heavy in all its parts; had never received any report that there was anything serious the matter with it, and it never needed anything but trifling repairs. He went through the bridge last September for inspection, examined it for two hours, and while so doing, two trains passed over. He says that he has made bridges a study for twenty-five years; that this one was put up in 1865, was considered above the ordinary run of bridges; that he doesn't know there was any objectionable feature, and that he had every confidence in the bridge. Mr. A. S. Rogers, in charge of all the carpenter work between Cleveland and Erie, corroborated Mr. Reid's testimony, and considered the bridge perfectly safe.

So much for the company's employees. The testimony of Mr. Joseph Tomlinson has somewhat of a different complexion. He testifies that h is now general superintendent of light-houses in the employ of the Canadian Government, and resides at Ottawa, Canada; that he was engaged in bridge building from 1840 to 1870, and made the drawings for this bridge. He did this under instructions from Mr. Stone. He never approved of a wrought iron Howe truss over a large span, as it makes an unnecessarily heavy bridge, and all the strains accumulate on the end braces. Notwithstanding its weight, it would have been a strong and durable bridge had the main braces been sufficiently strong. They were not made as large as originally designed, and it was his intention that they should be strengthened, but his connection with the company was severed on account of a difference that arose between himself and Mr. Stone concerning this bridge. He thought that the main braces were the only defective parts of the bridge. This was the only defect that he was aware of, except its unnecessary weight. He thinks it would have been an exceedingly strong structure had it not been for these defects. Mr. Collins (the present engineer) had nothing to do in any way with the bridge to his knowledge. The bridge was calculated to carry a moving load of two to three tons to the lineal foot. He was dictated to, in making his plans for the bridge, by Mr. Stone. If the iron had all been good, and wrought according to the patterns, and placed in their proper positions, he thinks the bridge would have been perfectly safe. In the original plan made by Mr. Tomlinson the braces were calculated to bear a pressure of four tons to the square inch. He was informed what alterations had been made in remodeling the bridge. He thinks that a pressure of four tons to the square inch on these braces would have caused lateral deflection. He proposed a method of strengthening the defective braces to Mr. Stone, to which Mr. S. would not listen, and even became angry. It was in consequence of this difficulty that he resigned his situation. Mr. Tomlinson never had any anxiety about the braces. He doesn't think a better set of rods or chords were ever put into a bridge.

We have, further, seen a published letter from Wm. T. Daly, traveling agent of the Toledo, Smith bridge company, to his employers. After giving the span and height of the truss, he states the following facts as the results of his own examination. "The top chord is made of five 6-inch I beams, varying from light 6-inch to extra heavy, with a web ⅞ inch thick. The braces are made of three pairs of 6-inch beams at ends, and three single ones at the centers; counter of two 6-inch beams. There are no beams over six inches in the bridge. The rods are eight, at each panel, varying from 1½ inch to 2⅛ inch rods. I saw five breaks in the top chord and braces, and about 26 breaks in the rods, and from the look of all the fractures there is no doubt with me as to what caused the bridge to give out. There are not any of the rods or top chord pieces or braces which have any fibre at all. It is almost as brittle as cast-iron. The lower chords at the ends are five in number, 1⅜ by 5 inches, laid horizontally, and, as there was no break in them, I could not judge of the quality."

As the bottom chord is entire, the fault must have been in some other portion of the bridge. The impressions of the last person cited above, as to the quality of the iron, there should be no difficulty in verifying. It looks as if a poor article was employed, and the depth of six inches is a small one for main braces some twenty-three feet long, even if supported by a counter at the middle of the length. The top chord too, apparently has no more depth. The design of the bridge should be thoroughly overhauled, and the quality of the material used should be tested. We hear that the railroad company are inclined to deny all claims for damages, for loss of life or injury, on the ground that the accident was caused by circumstances beyond their control, the storm and cold weather, rendering the iron weak. Such a defence will necessitate a careful examination of the wreck by competent persons, even if such an inspection was not resolved on before. Suppose that parties should erect a structure of "cold-short" iron, and, when it fell on some cold day, should claim that it was no fault of theirs. If the iron was poor the company cannot waive the responsibility for a bridge built in their own shops, by their own men. If the design was faulty, they are equally bound by the acts of their agents.

Would not this be a good time for the *Society of Civil Engineers* to bring up again, and press through to consummation the plan for a committee of engineers to examine and approve of every structure of this kind before it is open to public use. A careful inspection of existing bridges, and a criticism of plans for new ones, with proper tests after erection, will give the traveling public that assurance of safety which they do not now possess. It is fitting for the American Society to move in this matter, as they are the professional body who would have the most weight, and they are personally interested in the good repute of the profession and its proper elevation. As it is at present, there is scarcely any hindrance to parties building any structure they see fit, except the fear of pecuniary damages from an accident, of loss of business reputation as a reliable company, or as a question of dollars and cents in present outlay and future renewals. The inspection by railroad commissioners in some states amounts to something, but is not altogether satisfactory. There are many cases also, where railroads have been pushed to completion with scanty means, and temporary structures have been erected, to be replaced later; but lack of means and hard times necessitate a postponement of such improvements and a patching and *making do* which are hazardous to the public safety. As prevention is better than cure, we ought to be protected by better legal enactments and early inspection and oversight of all details on which safety depends, rather than to run the risk of life or limb, and then have the parties on whom responsibility can be fixed mulcted for damages. The public attention is so thoroughly awakened on this subject, that now is the time to act, and get proper measures passed.

THE full-sized details of top and bottom chord connections for the iron and the wooden bridges manufactured by Kellogg and Maurice, Athens, Pa., and exhibited by them at the Centennial Exhibition, with complete working drawings and strain sheets of both bridges, have been purchased by the University of Michigan for the Civil Engineering department. These models show a short section of top and bottom chords, with the eye-bars, pins, lateral bracing, floor-bearing, etc., of full size, but with the post shortened to some four feet in height.

AT a meeting in Detroit, last Saturday, of gentlemen interested in the tunnel project, the mayor and one of the aldermen were authorized to appoint a committee of experts to receive propositions from Gen. Wm. Sooy Smith and others, to report at a future meeting, and in the meantime Mr. Luther Beecher will take the initiatory steps for the formation of a tunnel company. Mr. Beecher said that the estimated cost of the tunnel proposed by Gen. Smith is $1,500,000, and, to give the project an impetus, he would guarantee to raise $500,000 of the amount, if the citizens would raise the balance.

THE Committee appointed by the Mayor and Mr. Chesbrough, the City Engineer, for the purpose of testing the West side Water Works of the city of Chicago, have been engaged on that important work during the present week. The following gentlemen form the committee: Chas. Hermany, C. E., Louisville; Moses Lane, C. E., Milwaukee; Thos. J. Whitney, C. E., St. Louis; Chas. H. Haswell, C. E., New York city; Henry Warrington, C. E., Chicago. The Quintard Iron Works Co., makers of the huge engines and machinery, a mass of between 700 and 800 tons weight, is represented by Messrs. Wilson and Sankey, and the attorney, Mr. F. Tuley.

The testing process being now in progress, we postpone a fuller account until our next issue.

CONDITIONS OF SAFETY IN PUBLIC BUILDINGS.

BY JAMES R. WILLETT, ARCHITECT.

The awful calamity in Brooklyn has stirred up the people everywhere. It was known to those who had given attention to the subject that theatres and public halls generally were deficient in many respects; but the burning of the Brooklyn theatre, together with nearly three hundred persons, has caused investigations to be made into the conditions of buildings intended to contain public assemblies throughout the country.

The principal conditions of safety to the audience in such buildings are as follows:

The building should be of ample strength in all its parts.

There should be separate, distinct exits of ample size, in each of the four corners of an auditorium, not only from main floor but also from each gallery, if there be any; these exits, and all stairs, etc., leading thereto, should be kept as far distant from other stairs and leading from the same floor, as is practicable.

There should also be a separate and distinct exit for every three hundred people in the building, and no door, stairs, passage, etc., should be less than five feet wide; if those at the four corners do not comply with this condition, then additional ones should be made.

Hand rails should be placed on both sides of all stairs, passages, etc.

Stairs should not be long and straight; they should have many landings and should alter their direction at each landing, but no winding steps should be put in. It is equally true that there should be no long straight halls.

The buildings should be entirely detached from others. If this is impossible then it should only adjoin another building on the side of stage or platform.

The main floor should not be more than a few feet above the grade of streets.

It is a mistake to suppose that a frightened crowd of people will get out of a building as rapidly as one which is not frightened; quite the contrary is the fact. When frightened, people press, crowd and overthrow one another until their fallen bodies form a barrier which prevents any egress whatever, it is perfectly idle to expect people to keep cool; some cannot do so, and when they struggle others will do the same.

It is, of course, impossible to make any building so

that an accident will never occur in it; but it is possible to make it so that a panic-stricken crowd cannot seriously injure many of themselves. The way to do this is by having numerous, separate, distinct and ample exits, and no building should be licensed unless it has them.

There are of course many other requirements that should be satisfied that we cannot state, but if the few we have named are observed there will be no repetition of any such great calamities happening in the future.

PRAIRIE CREEK BRIDGING.

While eminent civil engineers are designing strong, expensive structures to span the broad rivers and deep gorges of the world, either by solid stone arches, suspension, truss, or tubular bridges, there are multitudes of small streams to be bridged in a cheap, simple and substantial way.

Many of the creeks in the prairie states, in summer and early autumn, are dry, or nearly so; while in the spring they overflow their low banks and inundate a large extent of territory, necessitating long, low structures.

The common creek bridge is a framework in bents, each one having its mud sill buried in the soil or soft bottom of the water course. We think we have a better plan than the above. All our bridges, some of them three hundred feet in length, are on piling, set in rows crosswise of the road bed, and the rows far enough apart to make spans of the required length for the floor joist to be used. On each cross row of piling a cap is framed; upon these the bridge proper is constructed. If it is necessary that a wider span should be erected over the channel, a simple truss is used. Structures of this kind stand the ice, driftwood, and high waters, better than those on mud sills, and can be repaired more easily. But, says the thinking reader, "to build such structures a pile driver is required" which is expensive, unwieldy, slow in its operations even in the hands of experienced men, and to construct a few bridges the expense would be too great. This is all true. We did use one of these weighty machines for a few years,—till one of our practical farmers discovered a cheaper, more rapid, and a better way of doing the pile driving. All this work is now done with a twelve-inch post auger. This simple instrument in the hands of an experienced artesian well borer (of which there are a number in this county who have sunk hundreds of flowing wells) is used to sink a circular shaft the necessary depths, into which the p le is placed large end down, and sand filled in to hold it fast. In this way the work is accomplished with tools that can be moved from place to place with a pair of horses, and erected and worked by two men.

At places where there is but little travel, and a long high-water bridge too expensive to be constructed, we make low-water bridges in the way mentioned, fastening the roadway to the piling by strong iron bolts. These low water structures are inclined towards the water up stream, so the rising floods will flow on to the planking and tend to load it, rather than flow under and lift it.

What do you think of our way of setting piles and bridging in the prairie land? M. H. MESSER

ONARGA, ILL.

ANNUAL REPORT OF THE BOARD OF DIRECTION OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS, FOR THE YEAR 1875-6.—*Accepted Nov. 1st, 1876.*

The membership is:—

Honorary members, resident, 2; non-resident, 4; Corresponding members, non-resident, 3; Members, resident, 113, non-resident, 304; Associates, resident, 5, non-resident, 11; Juniors, resident, 7, non-resident, 44; Total, 484. Fellows, 70—of whom 10 are members and 1 Hon'y member—leaving 59. Total now connected with the Society, 552. On November 3d last, the number of proposals and applicants for admission to the Society was 23; the number of proposals and applicants during the year was 70; total number of proposals 93.

Of this number 2 were elected as Corresponding members, 50 as Members, 20 as Juniors and 2 as Fellows; 4 were laid on the table or withdrawn, and 6 are pending.

Of those who were elected, 1 Junior was proposed as Member; 4 Members elected before November 3d last, and 2 Corresponding Members, 40 Members, 18 Juniors, and 1 Fellow elected during the year, have qualified.

The increase during the year has been:

Corresponding Members, 2; Members admitted, 44—2 Associates and 2 Juniors became members, 48—less 1 deceased and 1 resigned, 46; Juniors, 18—less 2 became Members and 1 deceased, 15. Deduct—2 Associates who became Members, 2 Fellows deceased, less 1 admitted; Total increase, 60.

Twenty-one meetings of the Society were held during the year, one of which was the Eighth Annual Convention, and one—a stated meeting—held as an "officers' reception;" 10 were "regular" meetings, at which ballots for members were canvassed and other business done, and 9 were "stated" meetings, when papers were read and discussions had upon engineering subjects and generally time given for conversation.

Eleven stated and 3 special meetings of the Board were held during the year, generally for examination into the qualifications of candidates for membership, the application of the Society's funds, and similar general business of the association.

The Eighth Annual Convention was held in Philadelphia, June 13th, 14th, and 15th, accompanied by brief excursions to a few points of interest in the city, and a trip over the "New York & Philadelphia New Line" to New York and return.

Papers were presented to the Society during the year as follows:

Description and Results of Hydraulic Experiments with large Apertures, at Holyoke, Massachusetts, in 1874; Theodore G. Ellis. Efficiency of Steam Vacuum Pumps; J. Foster Flag. Note on the Resistance of Materials; Robert H. Thurston. Verrugas Bridge and the Method of its Erection; L. Lefferts Buck. The Portage Bridge; George S. Morison. The Practical Determination of Strains in the braced Arch; A. J. DuBois. Discharge of Water in Jets and Long Mains; Galen W. Pearsons. Notes and Suggestions on the Croton Water Works and Supply for the Future; Benjamin S. Church. Theory of Continuous Girders in Relation to Economy in Bridge Building; Charles Bender. Note on the Resistance of Materials, as affected by Flow and by Rapidity of Distortion; Robert H. Thurston. Fac Simile Telegraphy; Robert L. Cooke. A Water Conduit under Pressure; John T. Fanning. History of the Lehigh Coal and Navigation Co. and its Works; Robert L. Cooke. Determination of the Resistance of Railway Trains; Robert H. Thurston. Reconstruction and Enlargement of Cork River Tunnel; Max. J. Becker. Memoirs of American Engineering; John B. Jervis. Dams for Reservoirs—Shall they be of Earth or Masonry? William J. McAlpine. Connected Segmental Marine Boilers, a Demonstration of the Principles of their Construction; Charles E. Emery. Railroad Accounts and Returns; William P. Shinn. Qualities of Iron and Steel; William Metcalf. A Cheap Transfer Table; William P. Shinn. Gauging of Streams, a Special Case; David M. Greene. Cut-offs on the Mississippi River, their Effects on the Channel, above and below; Caleb G. Forshey. Laying Masonry in Cold Weather; J. Dutton Steele. Compressed Air Locomotives; J. Dutton Steele. Principles of Tidal Harbor Improvements, as applied at Wilmington, Cal.; Clinton B. Sears.

Reports were made to the Secretary during the same time, as follows:

Annual Report of the Board of Direction, on the Affairs of the Society, for Year ending November 3d, 1876. Award of the Norman Medal; Julius W. Adams, Chairman. On Tests of American Iron and Steel (2 reports); W. Sooy Smith, Chairman. On Change of the Society's Rooms (2 reports); John Bogart, Chairman. On Time and Place of the Eighth Annual Convention; G. Leverich, Chairman. On Organization of a Mutual Benefit Society; William E. Worthen, Chairman. On Policy of the Society; Alexander L. Holley, Chairman. On Securing a National Recognition of the Society; W. Milnor Roberts (for Committee). On Uniform Gauging of Streams in Connection with Observations of Rainfall; and On Failure of Dam at Worcester, Mass.; Theodore G. Ellis, Chairman. On Form Weight, Life and Manufacture of Rails; Ashbel Welch, Chairman. On Nomenclature and Classification of Masonry; J. James R. Croes, Chairman. On Resistance of Railway Trains; William P. Shinn, Chairman. On Technical Education; Henry R. Worthington, Chairman.

Discussions were had on many of these papers and reports when read before the Society; also on the following subjects:

Consumption and Waste of Water; Design and Erection of the Exposition Buildings; Docks and Wharves; Engineering Questions considered in the Location and Construction of the New York & Erie Railroad; Improvement of the Mouths of the Mississippi; Levees as a System of Reclaiming Low Lands; Metric System of Weights and Measures; Overland Telegraph to Europe; Professional Intercommunication; Progress of the Jetties at South Pass of the Mississippi; Waves of Translation that Emanate from a Submerged Orifice.

Many of these papers, reports, and discussions have been published in the Journal for the current year; also these papers presented last year:

Notes on the Improvement of the Mouth of the Mississippi; W. Milnor Roberts. Levees as a System of Reclaiming Low Lands; George W. R. Bayley.

Referring to the list of papers presented to the Society which were unpublished at the date of last report; of these, the following were published during the past year:

Experiments on the Tensile Strength of Steel Wire; Thomas C. Clarke. Levees as a System of Reclaiming Low Lands; George W. R. Bayley.

The following was omitted from the list:

Construction of a River Wall at Foot of Canal street, N. R.; William A. Radenhurst and John D. Van Buren, Jr., June 10th, 1875.

And the following presented and not published during this year are to be added:

Efficiency of Steam Vacuum Pumps; J. Foster Flagg, November 3, 1875. The Practical Determination of Strains in the Braced Arch; A. J. DuBois, November 30, 1875. Memoirs of American Engineering; John B. Jervis, February 1, 876. Fac-Simile Telegraphy; Robert L. Cooke, March 27, 1876. A Water Conduit under Pressure; John T. Fanning, April 5, 1876. Reconstruction and Enlargement of Cork River Tunnel; Max. J. Becker, April 15, 1876. History of the Lehigh Coal and Navigation Co. and its Works; Robert L. Cooke, April 19, 1876. Connected Segmental Marine Boilers, a Demonstration of the Principles of their Construction; Chas. E Emery, May 17, 1876. A Cheap Transfer Table; William P. Shinn. June 5, 1876. Principles of Tidal Harbor Improvement, as applied at Wilmington, Cal.; Clinton B. Sears, July 27, 1876.

In addition to these are several reports of Committees, upon a number of subjects, which still are unpublished.

During the year the Journal of the Society has been published monthly at a cost, for 1,000 copies each month, substantially as follows:

For printing, $2,512.05; Illustrating, $393.25; Copyright, $6.00; Total gross cost for 732 pages, $2,911.30. Deduct for 76 pages advertisements, $712.33; Net cost for 656 pages, $2,198.97; or $3.35 per page.

The "Proceedings" contain in addition to the reports mentioned—

Announcements of Meetings to be held; Topics discussed, etc.; Book Notes; List of Additions to Library and Museum; Lists of Members, with Addresses, Changes and Corrections; List of new Engineering and Technological Books; Memoirs of Deceased Members; Notes and Memoranda. Short articles on—American Bridge Construction; American Engineering at the Centennial; Bridges and Bridge Foundations; Centennial Commission of the Society; Committee Work; Compressed Air Locomotive; Concerning Conventions; Dams for Reservoirs; Determination of the Resistances of Railroad Trains; Discharge of Water from Jets and in Long Mains; Fall of an Iron Bridge; Jetties at South Pass of the Mississippi River; Laying Masonry in Cold Weather; Metric System of Weights and Measures; Selecting Papers to be Published; Sketches of Engineering Exhibits at the International Exposition; Tests of American Iron and Steel; Proceedings of the Board of Direction and of the Society; Statement of the Finances of the Society.

A List of Members of the Society, with their addresses was issued May 20th.

CORRESPONDENCE.

ASTORIA, LONG ISLAND CITY, N. Y., *Jan. 10th*, 1877.

EDITOR ENGINEERING NEWS:

SIR:—We were much interested in the article in your paper concerning surveyors, but should suppose from its general tone that you were more specially addressing land surveyors. If your criticisms refer to city surveyors they are certainly wide of the mark. We are sure that your paper has only to be known by the profession to be highly appreciated by every branch, and as you request communications from your subscribers we will be happy from time to time to furnish you with accounts of work being done and the methods and practice of city surveying as carried on in our section. Our office has been engaged for some years in laying out the city, and our work has embraced every variety of city practice, preliminary and detail topography, location of monuments, laying out of streets, avenues, etc., and a complete design for a system of sewerage, portions of which are now building. From actual practice we can send you information interesting to our friends in the west, and will, if you wish it, send on some illustrations for the photo-lithographer.

F. P. THOMPSON and
D. L. TAUNTON
City Surveyors.

EDITOR ENGINEERING NEWS:

SIR:—Permit me to state the following problem in the hope that some of your readers skilled in hydraulics can give me on answer:

Certain parties desiring to obtain water for steam purposes from a river some 750 feet distant, laid a two inch iron pipe from the boiler house and attached a small steam pump, which had previously lifted water from a well nearly if not quite thirty feet vertically. The pump was about 25 feet above the water in the river. The precaution was taken to fill the pipe with water, and the pump was then started. After it had drawn a large portion of the water from the pipe, it failed to get any more. As our informant stated it, "after pumping all the water from the pipe, none would follow from the river." Supposing that the pipe was not accidentally stopped at the lower end, a point which was probably attended to, why would not the pump fetch water.

The explanation which seemed satisfactory to the persons concerned, was that the friction was too great for the power of the pump, and they have since put up a windmill at a lower level. I fail to see how there can be any fluid friction before the water is set in motion, and as the friction is dependent upon the velocity, ought not the pump to draw water at some speed? X.

RISE AND PROGRESS OF AMERICAN ENGINEERING.*

[From the Proceedings of the American Society of Civil Engineers.]

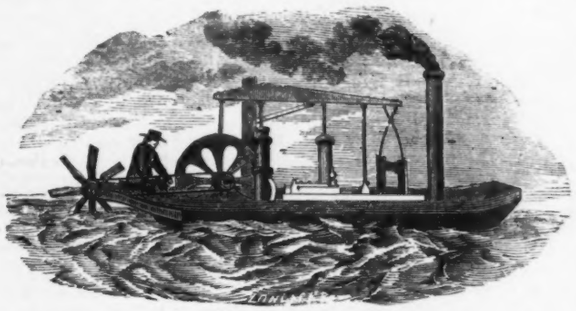
(*Concluded from page 18.*)

Locomotives soon came into general use. Baldwin commenced building them in 1833, and Morris soon after. Then came the Lowell shops in 1835, Rogers, Ketchem & Grosvenor, of New Jersey, in 1837. Then Winans, Mason, Hinckly & Drury, and the Taunton, South Boston, Manchester, Montreal, Lawrence, East Bridgewater, and numerous other works; all of which were busily occupied in furnishing engines for our rapidly extending railroad system.

The Harris engines were the first exported, and since then, locomotives have been sent in large numbers to England, Russia, France, Germany, Egypt and South America.

The railway system opened a new field for engineering, in the substantial structures required for bridges and viaducts, which everywhere were erected, too numerous even to mention here.

Timber bridges were generally erected, and the Burr, Long, lattice, Pratt and Howe trusses, have become identified with American engineering. The Howe bridge is perhaps the most remarkable system of framing, for strength and simplicity, that was ever designed for general use in bridges of all spans.



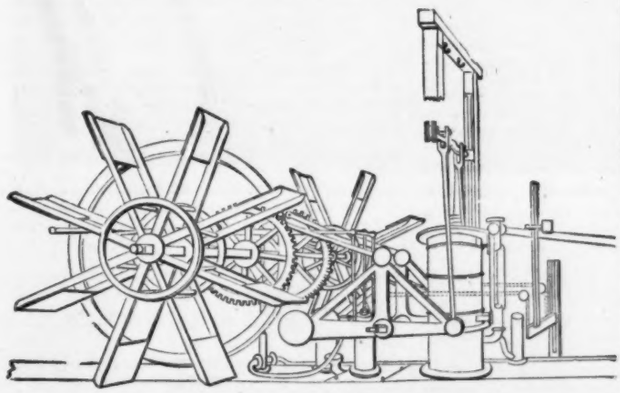
OLIVER EVANS' ORUKTER AMPHIBOLOS.

30 feet long and 12 broad. Cylinder 5 inches in diameter with a 19-inch stroke. Constructed by Oliver Evans about the year 1804.

The first iron railroad bridges were three spans, of about 55 feet each, erected on the Baltimore & Susquehanna Railroad, by James Mulholland, in 1846. These were plate girders. Iron suspension bridges had been previously used. The first in the country was erected by Mr. Finlay, over Jacob's Creek, in Pennsylvania, in 1796, and during the next 25 years about forty had been built on the same plan in different parts of the country.

A cast iron arch of 80 feet span had also been built over the Potomac Aqueduct by Maj. Delafield, in 1840.

Iron bridges, however, did not come into general use until a short time previous to the late war of the rebellion, when several roads, particularly the Pennsylvania, New York Central and New Haven, Hartford & Springfield, commenced replacing their worn-out wooden bridges with iron and stone.



THE MACHINERY OF FULTON'S FIRST STEAMBOAT.

Imported from England where it was constructed in 1805. Wheels 15 feet in diameter, cylinder 24 inches in diameter, 4 feet stroke.

The vast field opened to engineers by the building of railroads, and the incidental works, caused a great addition in numbers to the ranks of the profession, and engineering schools were opened in all sections of the country, which have graduated young men with excellent preliminary training for the profession, and have raised the standard of education for entering the practice of engineering far above what it was half a century ago. At the time of the height of the railway fever, every young man who shouldered a brass instrument was an "engineer." The spirit of the times now requires that he shall know how to use it.

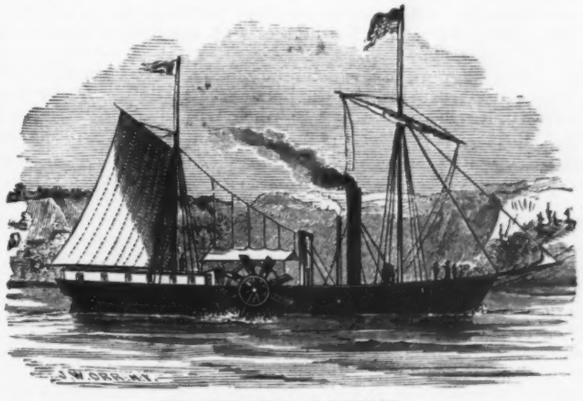
The railroad age culminated with the wonderful achievement of constructing a road through the uninhabited prairies and mountains to the Pacific ocean; a great part of it at the rate of a mile a day. To a European, it is something astounding that in a country just a century old, you can start from New York and ride 3,000 miles westward by railway, without changing cars; living, sleeping and eating on the train, and this chiefly through a country that half a century ago was almost wholly unexplored. Middle-aged men can remember when the Rocky Mountains were as much a "terra incognita" as the interior of Africa now is.

The railway system built up cities, and with their increase came water-works, pumping engines, systems of drainage and gas works, that in magnitude and in constructive excellence eclipse many of those of the old world. The number and magnitude of them is such as to preclude the possibility of naming them at this time. These works are so recent that they are known to us all, and their description fills our current engineering literature. The latest works of American engineers, such as the St. Louis bridge, over the Mississippi, the East river bridge at New York, and many others of less magnitude, but equal merit, the Pacific Railroad, the Hoosac and Chicago lake tunnels, and many other recent constructions, are works of which we may well be proud, as monuments of American engineering skill. Among the more remarkable works of American engineering may also be mentioned the military exploits of civil engineers attached to the army during the late war; the wonderful railway bridges built in a few days at Potomac Creek and elsewhere; the release of the fleet at the Red river; the canal at "Island No. 10, and the Petersburg mine.

In the short space of a century American engineering has risen to the highest standard, and ranks with that of any nation in the world. We have the longest railways, the best equipment and the most comfortable conveyances. We have by far the finest passenger steamboats in the world. We have the largest bridges, the greatest spans, and the deepest foundations, and the only successful railway suspension bridge in the world.

The question remaining to be solved is, what are we coming to? When will our improvements end? Can it be possible that a century from this time the American engineer can look back to such a record of progress as now appears to us? I reply, it is not only possible but probable.

In the age of wood and stone implements, who could have seen the progress of the age of bronze? In the age of bronze, when the pyramids were built, and vast works of years were undertaken, who could forsee the age of iron, with its great architectural and mechanical works? And who could have forseen the wonderful revolution upon the face of the earth that steam should produce?



THE NORTH RIVER, OF CLERMONT.

Robert Fulton's first steamboat as she appeared after being lengthened in 1808. She was launched in 1807, and was run as a regular packet between New York and Albany. Speed 4 miles per hour, length 133 feet, beam 18 feet, depth 8 feet, tonnage 160.

At the present time I sincerely believe that the days of iron and steam are numbered. What the next great improvement will be, we cannot now know; but the signs of the times point to solar heat as the motor that will drive steam from its stronghold, and aluminum as the metal that is to replace iron. The day will soon come when men will smile at iron bridges, engines and tools. Aluminum is the most abundant and best distributed metal on the earth. Every clay bank is a mine. Ways are already known how to reduce it, but with great difficulty and expense; as silicate of alumina, clay is one of the most refractory substances we have to deal with. Let but the discovery be made, how to reduce this metal cheaper, and we might well be astounded with the changes that would occur.

With a metal only 2½ times as heavy as water, 6 times as strong as steel, as easily worked as iron, and almost indestructible in air or water, conceive what would be the possibilities of engineering skill, to say nothing of the revolution in all the tools and utensils of ordinary life. Bridges of a mile span would be entirely possible; railway trains for passengers could be reduced to at least one-fourth their weight, and the navigation of the air (all except the alighting, in which I should never have great confidence), would become practicable. With a motive power which would not be obliged to carry so great weight of fuel as our present steam engines require, speed of navigation might easily be doubled. But these are merely visions in which a practical engineer of the present day has no right to indulge; he cannot yet afford to wait for the new discoveries that are to throw our works in the shade; like the builders of the pyramids, we must go on plodding in our old-fashioned way, leaving to those of our profession who shall look back upon us from the stand-point of the next century, to say if any of us shall be ranked among the "old masters."

* Address by Vice-President Theodore G. Ellis at the opening of the Eighth Annual Convention of the American Society of Civil Engineers at Philadelphia, June 13th, 1876.

ARCHES;

CONSIDERED GRAPHICALLY.

[Copyrighted 1877.]

(*Continued from page 16.*)

We have thought it better to presuppose that our readers had some knowledge of the equilibrium polygon and its properties, rather than to take up space with any more preliminary matter, and have gone over such ground as seemed needful to refresh the memory of the reader. If any one has failed to follow us thus far we would refer him to the numbers of "ENGINEERING NEWS" for Feb. 26 and March 4, 1876, or to "Graphical Analysis of Roof Trusses,"* which contains the articles referred to.

5. If the rib is made of a rigid material, the tendency to take a shape, other than the one to which it was first formed, will cause a bending action or moment at different points. Thus, between A and C, the rib will flatten somewhat, moving towards the straight line A C, and from C to B it will become slightly more convex. At C, where the rib coincides with the curve of equilibrium, there will be no tendency to bend. The bending moments on either side of a point where the curve of equilibrium crosses the rib will therefore be of contrary kinds or signs. It is necessary to know the value of the bending moments at all points, in order to so design the cross-section of the rib that it shall be able to resist them. The point C is not necessarily the crown of the arch; it happens to come near it in our figure.

If the arched rib is free to turn at its supporting points, there will be no bending moments there; if it is jointed or hinged at any place, as, for example, the middle, there will be no bending there; the curve of equilibrium must therefore pass through all such points. The rib may be so fastened at A and B that it cannot turn in a vertical plane, and there will then be bending moments at those points, as in the analagous case of a beam fixed at both ends, except for such a distribution of the load as makes the curve of equilibrium there coincide with the arch.

6. If the rib is hinged at three points, that is at the ends and middle, the curve of equilibrium is immediately fixed in position by the necessity of passing through these three points, and the problem of finding the stresses in the rib becomes very simple; but we prefer to suppose, at first, that the arch of Fig. 2 is jointed and free to turn at its ends only.

The stress diagram, 012, and the imaginary curve of equilibrium having been constructed, and the horizontal line H from O having been drawn, it will be seen that this line will divide the load line into two forces, the vertical components of the abutment reactions; for 2-0, the pull on A, is resisted by 0-5 and 5-2, the horizontal and vertical components at A, and, similarly, 0-1 is balanced by 1-5 and 5-0. The arrows in the figure denote these components, and we will call the vertical ones, analogous to the supporting forces of a beam, P_1 and P_2, as marked. We have here the usual closed polygon of external forces, as explained in the articles before referred to.

7. Let an imaginary vertical section be made at D F; from the theorem of moments, as equilibrium exists in this loaded arch, the moments of all the external forces must balance around any point, for instance the point E, where the plane of section cuts the rib. If the sum of the moments around E equals zero, the moments on one side of the plane must equal those on the other, and, as E is in the section of the rib, these moments can only neutralize one another through the moment of resistance of the section; consequently, the sum of the moments on either side must equal the bending moment at E. Then at E, if P_2 and H are the rectangular components of the reaction at B, and Σ W. L denotes the sum of the products of each weight by its horizontal distance L from E, the bending moment will be

$$M = P_2 . DB - \Sigma W . L - H . DE. \qquad (1.)$$

If the weights had been attached to the cord, or curve of equilibrium, we should have had, for moments on the right of and about F.

$$P_2 . DB - \Sigma W . L - H . DF. \qquad (2.)$$

But a cord, being flexible, can resist no bending moment. As this cord is the curve of equilibrium, there can be no tendency to move or no bending moment at any point, and expression (2.) must reduce to zero, or

$$P_2 . DB - \Sigma W . L = H . DF.$$

Substitute this value in (1.) and it becomes

$$M = H . DF - H . DE = H . EF, \qquad (3.)$$

which signifies that the bending moment at any point of an arched rib, under any vertical load, is equal to the product of the vertical ordinate from that point to the *proper curve of equilibrium* multipled by H from the stress diagram.

8. It will be noticed that, to the left of C, DF – DE will change sign, becoming negative, and therefore that the bending moment will change in direction, as stated before. If the rib becomes straight and horizontal, the point E moves up to D, and the bending moment becomes equal to H. D F, which is its value for a beam supported at both ends.

**Graphical Analysis of Roof Trusses: Greene*; Chicago, 1876, Geo. H. Frost, Publisher.

Such an arrangement of weights might be devised, continuously distributed along the rib, that there would be no tendency to change the shape of the arch at any point. The curve of equilibrium would then coincide with the centre line of the arch, and we should have what is termed an equilibrated rib. And, on the other hand, a rib can be designed for any given distribution of load, so as to be in equilibrium. This fact can be sometimes made use of when the load is definite, that is, not a moving load, and we shall refer to it again in the sequel.

9. It may have been noticed that, in § 7, we used the term *proper curve of equilibrium.* It has been stated that it is easy to draw, between A and B, any number of funicular polygons, which have their angles on the verticals let fall from the weights, by simply moving the point O horizontally in the stress diagram, and thus altering the value of H, the horizontal component of the tension. But the actual rib, under a given system of weights, must have a fixed value of H, and definite bending moments at all points; there is, therefore, but one funicular polygon which will be the *proper* curve of equilibrium.

Some conditions then must be imposed, and a sufficient one is that, supposing the points A and B to be fixed in position relatively to one another, the distance A B, or the span of the rib, shall be unchanged. An arch between two unyielding abutments satisfies this condition. If the curve A C is flattened by the pull on it, or by the bending moments by which it is urged towards the straight line A C, the point C will move a little to the right, while the portion between C and B will become slightly more convex. The movement of the point B, however, with reference to A, must be zero.

10. Consider the arched rib as disconnected from the points of support, but suspended in the air by the forces which were but now the reactions at those points. Equilibrium will still exist. The bending moment H. E F at E, from its effect on the particles at that section, causing an elongation of the fibres on one side and a compression of the fibres on the other side, produces what may be called an exceedingly small angle in the rib, or better a *change of inclination*, at E, moving the free end B, so far as this change alone is concerned, a very small distance in a direction perpendicular to a straight line from E to B. The amount of this displacement will depend upon the distance E B and upon the change of inclination at E, which change has just been shown to depend upon the bending moment H. E F. The amount, B R, of this change is greatly exaggerated in the figure. But the horizontal component, or projection, B S, of this displacement, which alone affects the horizontal distance of B from A, will manifestly, from the proportionality of the sides of the two right-angled triangles B R S and E B D, be to B R as D E is to E B, or B S will be proportional to D E. Therefore the horizontal displacement of B, from the bending at the section E of the rib, will be proportional to the product of the two quantities H. E F and D E.

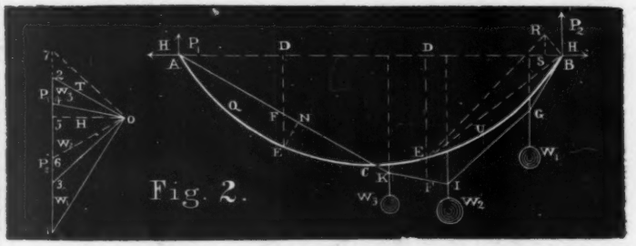


Fig. 2.

But this point may be, perhaps, brought out more plainly, if stated algebraically, thus—

$$BR \text{ varies as } EB . H . EF;$$

$$BS = BR . \frac{DE}{EB}; \text{ therefore,}$$

$$BS \text{ varies as } \frac{EB . H . EF . DE}{EB}, \text{ or as } H . EF . DE.$$

11. Taking all the points in the rib, the total horizontal displacement of B in regard to A would be proportional to $H . \Sigma EF . DE$, if Σ is the sign of summation of all the products E F. D E. As the span A B is to be unchanged, the above quantity must equal zero, and therefore, as H cannot be zero, we have the desired condition reduced to

$$\Sigma EF . DE = 0. \qquad (4.)$$

As E F changes sign when the curve of equilibrium crosses the rib, as at C, we arrive at this result for a rib free to turn, or hinged at its ends, that the *summation of the products E F. D E for every point where the curve of equilibrium lies on one side of the rib must equal the summation of all the similar products for every point where the curve lies on the other side.* Only one curve, manifestly, will satisfy this condition; for if we draw a new curve between A and B, we immediately increase one set of E F's and diminish the other.

(*To be continued.*)

THE INFLUENCE OF THE SEASONS ON ENGINEERING PROJECTS.

The severe cold which we have already experienced this winter, and the large quantity of snow which has accumulated in the Northern States, have given rise to the periodic feeling in many places that better means of communication are needed on some routes of travel. The remarks to this effect which have appeared in the public prints have brought to our notice how much influence the discomforts we experience at certain seasons of the year have to do with the urgent call for public improvements, and how, the immediate necessity for relief having passed away the improvement is postponed until another time.

The inconveniences which the business men of New York have had especially to submit to this winter, in going to and from their homes in the upper end of the island, by reason of the temporary delay and stoppage of street cars, has caused them to redouble their call for the speedy development of some of the schemes for rapid transit. The Gilbert Elevated Railway, already successfully operated for a considerable portion of its contemplated route, was taxed to its full capacity and was unable to supply the number of trains desired. By the way, we are pleased to see that a recent legal decision affords a good prospect that this road will now be permitted to extend its line over South Fifth Avenue. But the snow melts off or is removed in a few days, the public return to the old ways of conveyance, and the strong pressure for relief is relaxed.

When ferry-boats between New York and Brooklyn were wedged in the ice in mid-stream for several hours, crowded with passengers, while thousands were prevented from crossing, the cry for a bridge over the East River arose very strongly. The project was set on foot, and the bridge well under way. Then, through mismanagement, the funds were exhausted before the towers of the suspension bridge were up. After a check in the work of construction, another cold winter and an embargo upon the ferry-boats caused Brooklyn to see the necessity of putting her shoulder to the wheel, and the bridge again advances.

In a similar way, the difficulty which the steam ferries experience this winter in keeping open the passenger and freight communication between Detroit and Windsor, spurs up the tunnel scheme to new life. While the railroad companies which now cross the Detroit river by ferry would undoubtedly prefer a bridge, not only as probably less expensive than a tunnel, but also as likely to prove a hindrance to their great rivals, the navigation interests of the lakes, the city of Detroit is desirous of preserving both lines of business for her own benefit, and therefore favors a tunnel. But it requires a good cold snap and plenty of ice in the river to wake up the people of that city to the idea that they had better take a strong pecuniary interest in the undertaking. Whether a tunnel will be begun this next summer and pushed to completion, remains to be seen, but we feel confident that, if the Detroit river does not get clear of ice for a few weeks, the citizens will take vigorous hold of the project.

The interference with the usual land travel, which the deep snows of winter and what is known in some sections as "mud-time" of spring bring about, starts the agitation for the short lines and branches of railroad which we shall hear so much of for the next few months, and the building of which has been almost the only activity in this line for the past two or three years. In the settled months of summer we do not hear less of such schemes. Then we recall a city at the head of navigation on a river which is closed by ice for some four months in the year; a project for a railroad, extending some eighteen miles down the bank of the river to an open port, was discussed every winter for many years, two or three preliminary surveys were made at different times, one, we believe, more than sixteen years ago, but, with the going out of the ice in the spring, and the arrival of the first steamboat, public interest in the railroad would flag and die out. Finally, two or three years ago, the line was built, and the desired communication established.

Turning to the influence of another season of the year, we are reminded how the dry summers which we sometimes experience, while checking all vegetable growth, encourage the sprouting of a whole crop of water works schemes. When peoples' cisterns give out and their wells fail, they are thoroughly impressed with the necessity for a more reliable source of supply. They agitate, look round for practicable ponds or other points of beginning, appoint committees, and perhaps make some surveys and figure up the cost, but these moves take time, and, before long, the first soaking rain takes all the ardor out of the movement and it lies over until the next dry spell. Just the same fate awaits some irrigating plans every year. When the pressing need of the hour is satisfied, the enthusiasm is dampened most thoroughly.

The way in which so many projects have their ups and downs makes us think of the traveller who sought shelter from a sudden storm in a shanty much out of repair, which was conveniently near. Having found a spot where he would not be wetted by the drippings from a leaky roof, he suggested to the occupant that a few shingles, judiciously applied, might do much good; but the proprietor thought that he could not be expected to go out in the rain to make the repairs, while in pleasant weather they were not needed.

The parallel may not be considered very good, but some private and some municipal affairs are conducted much after this style.

THE ASHTABULA BRIDGE.

We give an abstract of the most important testimony which has been taken, in regard to the Ashtabula bridge, since our last notice, both before the coroner's inquest and before a Legislative committee which has recently commenced an investigation.

Before the inquest, Abraham Gotleib, C. E., of Chicago, chief engineer of the Keystone Bridge company for the western division, formerly chief engineer of the American Bridge company, and a member of the American Society of Civil Engineers, testified that he had made a careful examination of the Ashtabula railway bridge since its fall with the view of discovering the defective members. He was assisted in his labors by Mr. Cretore, of Cleveland. He presented a written report of his findings. After describing the structure very minutely and giving a table estimating the surplus or deficiency of material in the different parts of this bridge, he says the results show that all the members in the bridge except the top chord was excessively heavier than needed, even if the dead weight is assumed as large as 3,000 pounds per foot. The top chords shows in the four panels either side of the centre a lack of material. He finds that the strain on the top chord would be increased by the arrangement of the floor beams upon it. He says in reviewing the details of the construction: "I would like to state beforehand that the Howe truss pattern is not very well adapted for heavy iron bridges for railway traffic, for the simple reason that it contains too many compression members, which if properly constructed require much material, increasing thereby the dead weight of the bridge considerably. The bridge is less able to carry a live load if it has a heavy dead weight to sustain. When the wrecked bridge was constructed the building of iron truss bridges was in its childhood compared with the progress made since that time. The first objectionable point in the bridge, therefore, was the unnecessarily great dead weight. The second was the lack of sufficient sections in the upper chord; also, the manner in which the beams forming said chords were bound together, which brought much more strain on some of them than others." Judging from the position in which the train and bridge fell, he thinks the chances are in favor of the assumption that the vibration braces failed from some cause, the movement probably starting near the centre of the span. The prime cause might of been an engine or car off from the track or any sudden jar. Another possible cause of the rupture, he thinks, may have been a displacement of some of the top lateral rods, destroying in this way the top lateral bracing.

Mr. Joseph Tomlinson was recalled and stated that he had examined the wrecked bridge since the accident and found evidence on the angle-block that some of the braces had slipped out of place before it was last painted, some of them as much as three inches.

The engineer of the Canton Bridge Company testified that he thinks the main braces in the bridge were insufficient; that they contained enough material but were not of proper shape. He thinks that the set braces would have been very much stronger to resist compression if they had been connected throughout their entire length by plates of iron riveted to them. This was the method proposed by Mr. Tomlinson for strengthening them when the bridge was built. Some of the braces had been chipped at their ends to allow room for the rods, which chipping would weaken them somewhat.

Mr. Albert Congdon, who was master mechanic of the Lake Shore road at the time of the construction of the bridge, gives his evidence as to the curious way in which the construction and erection was looked after:

"I know something about the construction of this bridge, as I had charge of the work. In making the bridge I found a lack of material to fill the place for which it was designed. I told Mr. Tomlinson about it and he wanted to know if he had better let Mr. Stone know it. I told him he had better. A short time afterward I was told to take the plans and finish the construction of the bridge as I thought it should be done. I do not know how far the work had progressed at the time I assumed control. The braces were not marked to designate the position they were to occupy. I never calculated the strength of the tension or compression. I did not say much to Mr. Tomlinson or any other man about the bridge, as I did not consider myself a competent bridge man. From the time of Mr. Tomlinson's leaving I had the management of constructing the bridge. As soon as the bridge was completed it was shipped to Ashtabula. There was a recess in the angle block, into which the lateral braces fitted. The lateral braces on top of the cord were fastened to the outside of the angle block by a lug passing about three inches through the angle block. This description applies to the bridge before it was shipped. As soon as the bridge was shipped, Mr. Rogers told me that Mr. Stone had given orders to erect it, but he did not know how. I asked why he did not go and tell Mr. Stone so, and he said he did not like to. I then told him as much as I knew.

The Legislative committee appointed for the purpose took the testimony of Amasa Stone, Jr., former manager of the Lake Shore and Michigan Southern R. R. Among other matter he testified that he was the original designer of the bridge at Ashtabula, that he only superintended the plans, and there was no change of plans after the work was projected by him, but there was an error by the contractors which gave considerable trouble. A brace was put in horizontally, when it should of been vertical. A change in righting the braces was made before the bridge was finished. Mr. Stone says that the superintendency of the construction was in the care of Mr. Tomlinson, until he found him inefficient and discharged him. The bridge was then put in the hands of Mr. Rogers, who he thinks never had put together an iron bridge before.

The committee then examined Mr. Chas. Collins, chief engineer of the Lake Shore Road, who testified as follows:

"I don't know where the original plan of the bridge is except the one at Ashtabula before the coroner's jury. These are not the full working plans. I never saw those, however, they are generally preserved, but these were not. They belonged at my office, but about the time the bridge was constructed I was put at other work and this was put into the hands of another man. I never saw the plans, therefore, as they were not sent to my office. I think that they were up at the shop when the work was done. They would also be wanted when the bridge was set up. The examination of bridges belongs to a man under me. My instructions to the men are to report everything wrong. G. M. Reed is at the head of the examining corps. He has no set time, but works on a general order. Some time in September he reported verbally that the bridge was all right. They have not been required to report in writing on ordinary business. I never ordered any special examination of that bridge; never made any statements to the effect that the bridge was not mine but Stone's. I was once staying at Ashtabula and Mr. Rogers asked me to go and visit the bridge, and I told him the braces were in wrong, but told him that I had nothing to do with it. He requested me to have Mr. Stone come down. I went with Mr. Stone, and he remarked that he was surprised that the braces were in wrong; it was still resting on the trestle-work. When I saw it next it was completed. At the time it was tested the braces were afterward turned and an additional number put in. I made an inspection of it afterward when trains were running over it. I looked at it as an engineer, and thought the yokes about the angle-blocks would hold the braces in position. I did not anticipate any trouble on account of the position of the braces. I considered the fastenings of the braces sufficient. In the change that was made the corners of the braces were chipped off, but this I do not think would affect it materially. I have never made any estimate of the weight of the bridge. I have had no experience in building that kind of a bridge, but it would have been stronger if the braces had been united so as to make them act together

I have never known of another bridge to be built of wrought-iron on this plan. This bridge was an experiment. I think the upper cords were not all the same size. I never saw or examined the strain sheet of the bridge. I never myself made a mathematical examination of the bridge, with a view to ascertaining its safety. There was a guard rail which would prevent the wheel from jumping unless something had been tampered with. I think a locomotive might run across if there was anything wrong. Below the floor were beams or stringers. The bridge was built for a double track, the outside rail being immediately over the chord. The bridge would not be stronger if wider. It would have to be more than twice as strong for a double as a single track. I examined the wreck and found that some of the braces had slipped out of the angle-blocks. Since the accident I have been too busy with the erection of a new bridge to examine as carefully as I desire the material of the wreck. If one or more of the sway rods were to break, the floor would go one way and the train the other. The application of air brakes would be to check the train and, might possibly jump a car from the track.

We have been pained to learn that Mr. Collins, probably distressed beyond measure by this calamity upon a road under his supervision, with which he had been connected many years, shot himself in the head with a pistol, and was found dead in his house at Cleveland on the morning of January 19th.

We add an extract from the Cleveland (Ohio) *Leader* of Jan. 8, which, while not sworn evidence, probably contains some reliable facts:

A reporter of the *Leader* Saturday had an interview with a practical machinist and bridge-builder of this city, who was in the employ of the Lake Shore Company at the time when the Ashtabula bridge was constructed. As a machinist he worked upon the iron parts of the bridge while in the Cleveland shops, and as a draughtsman assisted in preparing some of the working drawings of the structure. His statement is as follows:

The bridge was built in the Lake Shore machine shops, in Cleveland. Work was begun on it in the Fall of 1864. Mr. Amasa Stone had control of the job, though a Scotch engineer named Tomlinson, figured the strains and made the drawings. The design was Mr. Stone's but the bridge was according to the Howe model, with the exception that iron was used in it for greater strength where wood was put in the ordinary Howe truss. When the bridge was built it was the first one in which that change had been made. The substitution of the iron for wood was then an experiment.

The bridge was completed and in position about the 1st of July, 1865. It was put together on supports, and when it was ready for the test, as was supposed, the workmen were ordered to remove the wedges. As they took these from under the bridge it began to settle. The superintendent of the work and others became alarmed, and ordered the men to stop taking out the supports. This they did, but if all the scaffolding had been removed the structure would undoubtedly have fallen of its own accord, it was so heavy. This defect was well known by the men employed upon the work at the time, but it was kept very quiet. No one knew anything about it if he were not present when the removal of the wedges was going on, or was intimate with the leading men employed upon the structure.

As soon as it was learned that a mistake had been committed several engineers made a thorough examination of the job. They found that the truss beams had been placed so that the strain would come on the broadest side, and that these beams should have been so put up that the weight would have fallen upon the narrowest side of the beams, that is, edgewise, or in the direction of their greatest diameter. As soon as this defect was discovered it was accepted as the great mistake in the bridge, and as the cause of the structure settling down when the supports were removed.

The defect in the structure having been discovered, men were set to work to change the truss beams, setting them up edgewise, and putting in four beams where there had been only three, and five where there had been four beams. Thus, while the bridge was made stronger, considerable was added to its weight. The bridge was finally completed in July, 1865, or about one year after the error was discovered. Correcting the defect was slow work since it involved the chipping off by hand of the bridge blocks, and the cutting of heavy beams so that they would clear the bolts.

About the 1st of July, 1866, the bridge was tested, preparatory to being put in use, in the presence of Mr. Amasa Stone, Mr. Charles Collins, now Chief Engineer of the road, and several other prominent gentlemen. But this test was with three engines, and not with six, as has been so often stated since the accident. As these were run on the bridge they weighed about forty tons apiece. At first they were run over the new work at a fair speed; then they were brought on the structure and allowed to stand. As the three engines came on the bridge it was depressed five-eighths of an inch, as measured by Messrs. Stone, Collins, and others. When the locomotives moved off the structure it sprung back three eighths of an inch, leaving it one-fourth of an inch from the original position. These measurements were made in the center of the structure. The test was apparently satisfactory to those who had the work in charge, and immediately the running of trains over the bridge was begun.

Mr. Stone blamed Mr. Tomlinson for the error, and said: "I can't see how so serious a defect in the drawings slipped my eye. I had it in my mind from the beginning that the beams were to be set edgewise instead of flat, as they are now placed." The beams were of wrought iron, and of the form known as the "double R." The placing of such beams with their flat sides toward the superincumbent weight, was, therefore, a serious blunder and had to be radically reformed.

The gentlemen who made the above statement says that he was not present when the supports were removed, but that he was told by several who were present and who were employed upon the work that the trouble was as above stated. He states further that at the final test he was present by invitation of Mr. Stone, and is positive as to the number of engines used in the test, and as to the depression of the structure. He also says the stone work was good with the exception of the west arch, in which there was a crack near the keystone at the time of the test. This, however, he thinks was of little account.

He thinks the great trouble in the bridge was in its weight, which was altogether too great. He also believes the beams should not have been extended beyond the angle blocks, and that in making the change the work was patched up, not thoroughly rebuilt.

We notice frequently, in our exchanges, that roofs have given way in many places throughout the North, from the unusual accumulation of snow. Any structure, in this latitude, should have such an additional load provided for when the design is made.

It is expected that the series of tests applied to the West side pumping engines of Chicago, under the supervision of the committee of experts noted by us in our last, and which have been in progress for the past two weeks, will be completed by the date of our present issue.

We omitted to answer last week our correspondent "F" respecting the location of the quarter corner on the north line of the section shown on page 14 of the News. Having located the northeast and northwest corners of the section by the "jogs" as given in government figures, we would divide the actual distance *pro rata* to the distances as given on the government plat, *disregarding entirely* the existence of the quarter corner to the section north of the town line.

A meeting of persons interested in canal navigation was held, a few weeks since, at Buffalo, to see what measures could be taken to improve the efficiency of these waterways and to revive the traffic. The Belgian system of towing by cable on the bottom of the canal was strongly advocated, and additional steps were suggested for inaugurating such a system; but it was stated that there was already no legal hindrance to the introduction of the plan, and that whenever any one wished to introduce train boats they could do so. One party urged the laying of a T rail upon piles on the tow path, using small locomotives for traction,

---

It has been considered very desirable that some efficient means should be found of making one of the wheels on a car axle run loose, as the tractive force on curves will then be sensibly diminished, while the wear on wheels and rails will be very much less. The testimony of Mr. R. W. Fowler, Jr., General Manager of the Philadelphia West End Passenger Railway Co., who had special charge of the narrow-gauge railway at the Centennial Exhibition, is very satisfactory as to the working of the Miltimore wheel and axle. He reports that seven of the thirty-six cars on this road were equipped with this wheel and axle, doing their full share in transporting over four millions of passengers. The gauge of the track was three feet, length three and one-half miles, almost entirely curves, some of 250 ft. radius on grades of 155 ft. to the mile. Six loaded cars with these wheels and axles were drawn with twenty-five pounds less steam than five cars with rigid axles, although each truck of the former cars weighed 3000 pounds more than those under the latter. The tread and flange of a Miltimore wheel, to which the Westinghouse air-brake was applied in making 160 stops daily, show no perceptible wear, while a rigid wheel shows much abrasion. Journal brasses and brake shoes were renewed twice, in some cases, with the rigid wheels, but not even once with the Miltimore wheels, nor were there any hot boxes. There were no renewals: the journals were lubricated but twice in six months. Black oil was used a portion of the time, and then Albany grease. Mr. Fowler is of the opinion that the life of car wheels so mounted must be doubled, with a corresponding saving of wear on the rails, and with but slight difference between the life of rails on curves and on straight tracks. We take these facts in substance from the *National Car Builder*.

From the annual message of the Mayor of Detroit Mich., we extract a few items which will probably be of interest to the profession:

Wood pavement laid in 1876, 106,375 sq. yds.; stone pavements 27,865 sq. yds., at an average of about $1.20 per sq. yd. Experience teaches that wood pavement is a failure. In some streets where it has been laid not over six or seven years, th repairs that have become necessary, amount to almost as much as it would cost to put down new pavement. It is far too expensive to continue its use longer, except perhaps in a few streets that are used for pleasure driving, and around the public library and court h uses; and even then the gutters should be of stone and the center of cedar.

Public sewers, built in 1876, 5 miles and 4,294 feet, and cost $148,425.03, or an average of about $4.84 per lineal foot which includes $4,811.11, the cost of 218 receiving basins; 178 other receiving basins were built at a cost of $9,085.12. Lateral sewers, 7 miles, 1421 ft., averaging 67 cents per lineal foot.

It is a matter of just pride to the citizens that the Board of Water Works have, during the past year, not only paid their running expenses, interest on their bonded debt, laying of pipes and all improvements connected with the old works, but have in addition, a surplus left to apply on the building of the new works. I have no fear, if the commission remain as now constituted, but that the whole debt created for the purchase of land in Hamtramck, will eventually be paid by the Board without resorting to taxation.

The average daily quantity of water pumped was 11,200,000 gallons. No. of families assessed for water rates, 20,466. No. not assessed, 316! The total pipeage of the works is 198 miles, of which two miles were laid the past year for the new works, and eight miles for the present works. Operating expenses $53,119.64. Amount expended in constructing new water works, to Jan. 1, 1877, $675,832.88. They will be put in operation the present year.

The Board of Health, as at present organized, has not perhaps accomplished as much as could be desired. Its powers, without doubt, could be enlarged so as to include in its functions the supervision over the drainage and ventilation of dwelling-houses, the defect in which yearly causes scarlet, typhoid and other fevers. The offensive odors and poisonous gases that emanate from bath-rooms, fixed basins and water-closets, and are now conveyed to our bed-rooms and other apartments, could with proper care be made to escape into the open air. Persons contemplating building should be required to submit plans of the drainage of their premises to the Board, and if in accordance with the regulations, it should be their duty to furnish a certificate to that effect. I am fully satisfied that defective drainage causes more sickness in this city than all other causes combined, and it is a matter to be regretted that the Board of Health have not ere this taken the matter in hand, as I believe it requires our most urgent and immediate attention.

The street opening law should be so guarded as to protect the tax-payers from the manipulations of the speculators, as through their efforts it not unfrequently occurs that miles of streets are opened (which, so far as the public interest is concerned might better remain closed), for the sole purpose of benefitting some particular one's five-acre lot.

REGULAR MEETING OF THE CHICAGO CHAPTER A. I. A.

Held Thursday, January 18th, 1877, 2:30 p. m., at the Secretary's Office, 90 LaSalle Street.

Roll called. Motion made and seconded to suspend the reading of the minutes of the last meeting. Carried. Announcement was made of the death of Mr. Asher Carter formerly an active member of the Chapter, and a motion was made and seconded that a committee be appointed to draft appropriate resolutions. Carried. The President appointed Messrs. F. B. Hamilton and Henry L. Gay. who presented the following resolutions and memoir which was unanimously adopted by the Chapter, and the Secretary ordered to present copies for publication to Engineering News, *American Architect*, and the daily Chicago papers, and a copy of them to be sent to the widow of the deceased:

Resolved, That the Chicago Chapter of the American Institute of Architects does hereby extend its sympathy and deep regret to the relatives and friends of the late Asher Carter, and that by his death there has been removed one who has ever upheld the dignity and honor of the architectural profession, and who, through his quiet and studious devotion to his professional duties, has earned the honor and respect of his colleagues.

Resolved, That the Chicago Chapter, fully knowing

the merits and noble qualities of the deceased, particularly extends its sympathies to his bereaved widow.

Mr Carter came to Chicago in the year 1849, under a commission to superintend the erection of the Second Presbyterian Church, which was located on the corner of Washington street and Wabash avenue, long and familiarly known as the "Spotted Church," which was the first important structure erected in Chicago from studied designs of an architect, the plan having been made by James Renwick, of New York. Mr Carter having become permanently located in Chicago during the superintendency of this church, continued his profession here up to the year 1873, during which time he made three different partnerships, viz., with Mr. Augustus Bauer in the year 1855, which continued till 1861, after with Mr. W. H. Drake, which continued till after 1871, when Mr. P. B. Wight, of New York, joined the firm, with the firm name of Carter, Drake & Wight, which partnership was disolved in the year '73, Mr. Carter retiring entirely from active business.

Mr. Carter has been directly connected and interested in the erection of many of the mercantile buildings of Chicago, together with a number of residences, churches and school buildings.

HENRY L. GAY, *Sec.*

ERECTION OF THE VERRUGAS BRIDGE.*

BY L. LEFFERTS BUCK, C. E.

In an article from the *Railroad Gazette*, September 11th, 1875, headed "Rapid Renewal of Bridges," appears an extract giving inquiries made by Mr. J. Dutton Steele, regarding the plan of erection of the Verrugas Bridge. I was in charge of the work as engineer, from the laying of the first stone to completion. The plans followed in its erection were my original design. Articles have appeared in different papers at various times describing the work; but none that I have ever seen gave a very clear idea of the manner in which it was handled, or the difficulties encountered. Hence, I present the following:

The Verrugas Bridge is situated on the Lima & Oroya R. R., in Peru, S. A., 51.8 miles from Callao. The mean elevation of its grade line above sea level is 5,836 feet, The ravine or *quebrada* which it crosses, furnishes a channel for a very small stream or rill, which coming from the mountains by a rapid descent, and flowing nearly northward, is discharged into the Rimac river, about 800 feet north of the bridge.

The earth in the vicinity of the bridge is a sort of concrete. The west side is the hardest, and is composed of water-washed granite, boulders, cobblestones and pebbles, very closely packed, and the interstices filled with a cementing material, which, undisturbed, is very hard. It requires blasting for its removal. The east side is not quite so hard, having some streaks of bluish clay; but it is pretty thoroughly mixed with rough stones resembling in texture the "blue stone" of which curbs are made in New York. It is very compact and furnishes a good foundation, especially in a dry climate like that at Verrugas. The sides of the ravine are very rugged.

The bridge consists of three iron piers, four iron spans and two stone abutments; in height, pier No. 1 is 179 feet, No. 2, 252 feet, and No. 3, 146 feet; the abutments are 42 feet each, span No. 1 is 125 feet, and spans Nos. 2, 3 and 4 are each 100 feet long. The total length of bridge from centre to centre of end pins, is 575 feet; of which 425 feet is made up by the four spans, and the remaining 150 feet by the three piers. The spans are all "deck" with Fink trusses.

Each pier is composed of three transverse bents, of four columns in each bent, making twelve in each pier. Each column is supplied with a cast iron foot, resting upon a firm pedestal of granite masonry; each pedestal having an area of base and depth proportionate to the nature of the soil in which it is placed. The piers are built up in sections or stories of 25 feet each. At each joint is a casting with a tenon on each end. This casting forms the joint connecting the pieces of the column, and the intersections of the latter with the transverse and longitudinal struts, and the tie rods by which the pier is braced. All columns are what is known as the "Phœnix."

The bridge has a grade of 3 per cent. Provision is, however, made by which all wall plates, bridge seats and roller beds are level.

There would have been considerable risk of error in locating centres of piers and abutments by direct measurement. I therefore first located them by triangulation; setting two monuments opposite each point, at right angles to the bridge line. Then finding a piece of level ground, I measured off a line; putting in stakes corresponding to abutment faces and pier centers. Over this was stretched a small flat steel wire, with one end made fast, and the other passed over a pulley, and having a weight attached to this wire, vertically over each stake, a tag was secured. The whole apparatus was then taken down and the wire stretched across on center line of bridge. Next, by setting up the transit opposite each point, sighting to these tags, and then plunging the telescope, an accurate correction of distances was made.

As the original plans and apparatus for erecting the iron-work have been described in other articles and are pretty well understood by mechanical engineers, it is unnecessary to speak of them here. I believe the only difficulty in using them, would have arisen in getting the material for the piers and the two middle spans down into the bottom of the ravine, and then having to hoist it all to the various positions the pieces were to occupy. I do not think that there could be the least doubt as to their safety. They were, however, abandoned and my own plan (as below described) adopted.

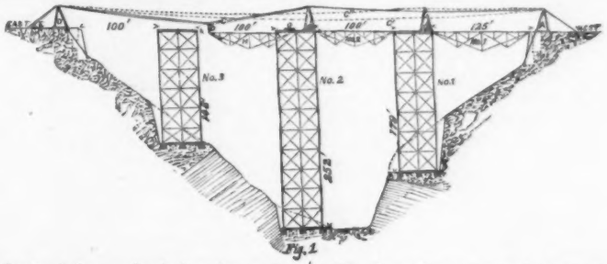

Fig. 1

A sketch (Fig. 1) shows a side elevation of the work in progress; together with the cables, temporary span, etc., and another (Fig. 2), a transverse view of the top section of one of the piers, showing end view of tem porary span. *A* and *D* are two wooden towers, standing on the ground just back of the abutments, and having a height of 30 feet. These towers supported two sets of wire cables—one set vertically over each truss line. The ends of the cables were securely anchored to sticks of timber set in the ground outside of the towers. The position of the cables at the beginning of the work is shown by dotted line *c*. Each cable was supplied with a traveler, *b*, to which was attached a set of block tackle, whose "fall" end was passed over tower *D*, and on to the drum of a winch at *E*. When the tackle was loaded, the strain on the fall was sufficient to haul the traveler out. A tail rope passed from the back end of the traveler over the top of tower *A* and around a cleet, near which a man was stationed for the purpose of paying out or hauling in as was required. *a'* and *a''* show the positions of a third tower used as the work progressed, for the purpose of shortening the span of cables; *c'* and *c''* the respective positions of the cables. H represents the temporary span used to support the iron-work of permanent spans while they were being put together. This temporary span was not used till after all the piers and span No. 1 were completed. It was constructed as follows:—Chords and posts of yellow pine; chains of round iron rods; lateral and diagonal bracing of wood. Its width was such as to allow it to pass between the inner columns of the top section of the piers, by leaving out the diagonal tie rods of the section as shown in (Fig. 2).

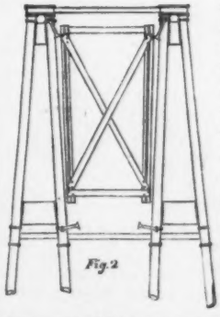

Fig. 2

The materials for the bridge were unloaded from the trains at the west or Lima end of the bridge.

In erecting pier No. 1, the columns, struts, ties, etc., were moved on "push cars" to the abutments, where they were put together—one pair of columns at a time with their joints, castings, transverse strut and tie rods. A piece of plank was lashed across the lower ends of the columns to steady them. The blocks were then lowered from the travelers and made fast to the upper ends of the columns; when the men at the winches raised the load clear of the abutment, the tail ropes were paid out, the columns thus carried out over the pier and set standing in position ready for bracing.

After pier No. 1 was complete, span No. 1 was laid in position, on a scaffolding, built up from the ground. Tower *a'* was then set up, and the material for the other piers run out and put together in front of *a'*. Pier No. 3 was erected next, and pier No. 2 last.

The three 100 foot spans were laid on the temporary span. As soon as one of these was swung up, the temporary span was moved forward to the next opening; the forward end being carried by the travelers, and the back on the iron-work. This operation was repeated for each of the spans.

The time taken to erect the iron-work was three and one half months. Everything worked satisfactorily. Not a man was seriously injured; and the only casuality was the falling of one piece of column by getting loose from the strap. It struck on a stone and was badly broken; but was, however, repaired in such a way as to be as strong as ever.

The excellent manner in which the work went together is evidence of the great care taken by the constructors who furnished it, of their attention to the minutest details of the plans, and of their thorough inspection of the work.—*Baltimore Bridge Co.*

*A Paper read before the American Society of Civil Engineers, Dec. 1st, 1875

MINING TIMBERS.

Some attention is at length being given to the subject of preparing timber for mines in a manner to increase the length of their life. From eight to ten years in mines comparatively dry is enough to weaken timbers to such an extent that they become unsafe and must be replaced. In veins of ordinary size the stopes may be abandoned when filled up, but inclines, shafts, permanent adits, and all working ways need re-timbering at least once in ten years.

In America this question is now becoming one of considerable importance. A number of large mines that were discovered in the early days, are now undergoing repairs, and if the present system of timbering is preserved in the future, the industry will be forced to carry a very heavy additional expense, which will amount to millions annually, and which may be decreased to a large extent by adopting the proper precautions in all future work.

It may be accepted as a rule that woods containing the least water in their composition will give the best results when used raw. The following table gives the comparative proportion of water in the various trees:

Willow	26 per cent.	Horse Chestnut	38 per cent.
Sycamore	27 do	Red Beech	39 do
Mountain Ash	28.3 do	Pine	39 do
Ash	28.7 do	Alder	41 do
Birch	30.8 do	Elm	44 do
Oak—ordinary	34 do	Red Pine	45 do
White Oak	36 do	Larch	48 do
White Pine	37 do	White Poplar	50 do

The following rules should be adopted in selecting trees for heavy timbers:

1. Never cut trees from a marshy or damp soil.

2. Wood cut from a hill side is denser than that growing in a valley or on an open level ground.

3. Select the trees in July or August. At this time of year it is easier to choose the soundest and most healthy.

4. Never cut a tree that has not attained its full growth.

5. In selecting timber, choose that well filled out with leaves and branches at the top, and whose bark is even, firm, and of a uniform color.

6. Cut the tree as near as possible to the ground, for the lowest part is the best wood.

7. Immediately on felling, the tree should be stripped of bark, its limbs cut off, the sap wood removed, and supports placed under it to raise it from the earth.

8. Allow the logs to lie for a year to season. If they are left where they fell, raise them clear of the ground, and take away all bushes, etc., from around them. If the logs are hauled to the vicinity of the mine to season, pile them up on skids, putting a strip of 2-inch timber between each layer, so as to allow a free circulation of air around them. The pile should be covered with a shed.

9. It is advantageous to soak logs for a week or two immediately on felling them. The liquifaction and removal of the sap is thereby hastened. It is also advantageous to allow logs to season for two and even three years if possible.

If the above rules are carefully followed, the life of a mine timber will be prolonged from five to seven years.

Of late years, experiments for the still farther preservation of wood by chemical processes have met with excellent success, and the prepared woods are now used to a considerable extent in railroads, etc. There are numerous patents for this process. Chloride of mercury, chloride of zinc, sulphate of copper, creosote, pyrolyneous acid and various bituminous vapors are used, all with good results.

All these, however, require rather extensive works for their application, and connot be advantageously employed by a single mine. There is an excellent field for enterprising men in our various mining centers in the business of preparing mine timbers, and it is singular that the opening has not been filled before this. Timbers after being well seasoned and prepared chemically by any of the well recognized methods, are worth double the cost of the raw material, while the expense of preparation is about nominal outside of the first cost of the works.

There are a few good plans for adding a few years to the life of even seasoned timber without chemical preparation. The best of these is to paint the wood well, and while the paint is damp, sprinkle with sand.—*The Mining Review.*

[From the City Record.]

DEPARTMENT OF PUBLIC WORKS,
COMMISSIONER'S OFFICE, ROOM 19, CITY HALL,
NEW YORK, January 18, 1877.

To the Honorable, the Board of Aldermen:

GENTLEMEN—I have the honor to acknowledge the receipt of your resolution of the 11th ult., requesting me to report to you as to the advisability and practicability of permitting the Street Cleaning Bureau to open the manholes of the several sewers after each snow storm and emptying therein the accumulation of snow and ice from the streets of this city.

In reply, I beg to state that the unauthorized use of the sewers and receiving-basins for this purpose has been a source of much trouble and expense whenever it occurred. As an instance, I will mention that the manholes of the sewer in Broadway, between Washington place and Fourth street, were opened and filled with snow and ice by men of the street cleaning force in March, 1875, completely stopping up the sewer and causing the flooding of the adjacent cellars. The solid deposit thus formed had to be taken out by hand at great expense.

The number and capacity of the sewer manholes is very small in comparison with the quantity of snow and ice which accumulates in the streets. Many of the old sewers in the lower part of the city were built without manholes, and those that were recently put in to facilitate examinations and repairs are few, and only large enough to give access to the sewers.

Of the small quantity of snow and ice that could be put in the manholes, only a small proportion would be melted, as the temperature in the sewers would soon be reduced below the melting point, and the balance, remaining solid, would stop all drainage.

The most effectual way in which the sewers can be made to contribute to the removal of snow and ice from the streets, is by keeping the gutters, culverts, and mouths of receiving-basins unobstructed. The attention of the Police Department was recently called to this fact, and they promptly responded by approving the suggestions made.

From the foregoing, it is very clear that the emptying of snow and ice into the sewer manholes is altogether unadvisable, and should not be permitted.

Very Respectfully, ALLAN CAMPBELL,
Commissioner of Public Works,

The Block system of signals has been extended upon the Pennsylvania Railroad upon its main line from Philadelphia to Pittsburg, and also upon the New Jersey division.

SURVEY OF THE PUBLIC LANDS—HOW TO TELL TOWNSHIP AND SECTION CORNERS.*

BY JAMES EDMUNDS,
[*General Land Office, Washington.*]

It is proposed in the present article to give a general outline of the system adopted by the Government for the survey of the public lands, the method of running and marking the lines, the approved methods of running lines and establishing corners additional to those required by law to be actually run and marked in the field, and the rule for re-establishing obliterated corners.

The first public surveys were made under the ordinance of May 20, 1785. The townships, six miles square, were laid out in ranges extending northward from the Ohio river, the first township in each range being numbered one. The region embraced by the surveys under this law forms a part of the present State of Ohio, and is usually styled "The Seven Ranges." In these initial surveys only the *interior lines* of the townships were surveyed, but the plats were marked by subdivisions into lots of one mile square, and mile corners were established on the township lines. The lots were numbered from 1 to 36, beginning in the southeast corner of the township, and each succeeding range of sections began with the number next to that with which the preceding one concluded. In fractional townships the lots bore the same number as if the township had been entire. The surveys were made under the direction of the Geographer of the United States.

The act of Congress of May 18, 1796, (U. S. Statutes-at-Large, vol. 1, page 464,) provided for the appointment of a surveyor-general, and directed the survey of the lands northwest of the Ohio, above the mouths of the Kentucky, to which the Indian title had been extinguished. Under this law *one-half* of the townships surveyed were subdivided into sections by running through the same each way parallel lines at the end of every two miles, and by marking a corner on each line at the end of every mile. The sections were numbered by beginning with number one in the northeast section, and proceeding west and east alternately through the townships to the thirty-sixth section in the southeast corner of the township. This method of numbering sections is still in use.

A TOWNSHIP.

6	5	4	3	2	1
7	8	9	10	11	12
18	17	16	15	14	13
19	20	21	22	23	24
30	29	28	27	26	25
31	32	33	34	35	36

The act of May 10, 1800, (Statues, vol, 2, page 73,) directed the subdivision of townships into half sections of three hundred and twenty acres each, by running parallel lines through the same from east to west and from north to south, at the distance of one mile from each other. Upon the lines running east and west corners were established at every half mile, and upon those running north and south at every mile. It was provided in all cases where the interior lines of the townsphips exceeded or did not extend six miles that the excess of deficiency should be specially noted and added to or deducted from the western and northern ranges of sections, according as the error occurred in running the lines from east to west or from south to north. The act also provided for the subdivision of all previonsly-surveyed townships, the interior lines of which had not been actualy run and marked in the field.

The act of February 11, 1805, (Statues, vol. 2, page 313), directs the subdivision of the public lands into quarter sections, including those townships subdivided under the act of May 18, 1796, above referred to, and provides that all the corners marked in the surveys shall be established as the proper corners of sections or subdivisions of sections which they were intended to designate, and that corners of half and quarter sections *not marked* shall be placed as nearly as possible equidistant from those two corners which stand on the same line. This law declares that the boundary lines actually run and marked in the field shall be the proper boundary lines of the sections or subdivisions for which they were intended; that the lengths of such lines as returned by the surveyors shall be held and considered as the true lengths; and that the boundary lines which shall not have been actually run and marked shall be ascertained by running straight lines from the established corners to the opposite corresponding corners; but in those portions of fractional townships where no opposite corresponding corners have been or can be fixed, the said boundary lines shall be ascertained by running from the established corners due north, south, east, or west lines, as the case may be, to the external boundary of such fractional township.

The act of April 24, 1820, (Statutes, vol. 3, page 566), provided for the subdivision of sections into half quarter sections by north and south lines, fractional sections containing more than one hundred and sixty acres to be subdivided under rules prescribed by the Secretary of the Treasury, but fractional sections containing less than one hundred and sixty acres would not be subdivided.

The act supplementary to the several laws for the sale of the public lands, approved April 5, 1832. (Statutes, vol. 4, page 503), directed the subdivision of the lands into quarter-quarters; that in every case of a division of a half quarter section the dividing line should run east and west, and that fractional sections should be subdivided under rules and regulations prescribed by the Secretary of the Treasury. Under the latter provision the Secretary directed that fractional sections containing less than one hundred and sixty acres, or the residuary portion of a fractional section, after the subdivision into as many quarter quarter-sections as it is susceptible of, may be subdivided into lots, each containing the quantity of a quarter quarter-section as nearly as practicable, by so laying down the line of subdivision that they shall be twenty chains wide, which distances are marked on the plat of subdivision, as are also the areas of the quarter-quarters and residuary fractions.

The two acts last above mentioned provided that the corners and contents of half-quarter and quarter-quarter sections should be ascertained, as nearly as possible, in the manner and on the principles directed and prescribed in the second section of the act of February 11, 1805.

PROJECTION OF SURVEYS.

Under the surveying laws and the existing regulations of the Depaatment the surveys are projected in the following manner: The initial point for the surveys within a given surveying district having been determined upon, a *principal base* line is surveyed on a true parallel of latitude east and west therefrom, and on said line quarter-section, section, and township corners are established at every forty, eighty, and four hundred and eighty chains, respectively. The corners thus established are for section and townships north of the base, but not for those on the south. The *principal meridian* is extended due north and south of the initial point, and similar corners are established thereon, which are common to the townships lying immediately east and west. The law requires that the meridional lines shall be run on the true meridian; therefore, in order to counteract the error that would otherwise result from the convergency of meridians, and also to check errors arising from inaccuracies in measurements on mer dian lines, *standard parallels* or *correction lines* are run and marked at every four townships, or twenty-four miles, north of the base, and at every five townships, or thirty miles south of the same. Guide meridians are next surveyed at intervals of eight ranges, or forty-eight miles, east and west of the principal meridian, starting north of the base, in the first instance, from that line and closing on the first standard north; then starting from the first standard and closing on the second standard north, and so on. South of the base line the guide meridians start from the first standard south and close on the base line; then starting from the second standard and closing on the first standard, and, again, starting from the third standard and closing on the second, and so on. The closing corners on the base lines and standard parallels are established at the intersection of the meridional lines therewith, thus, owing to the convergency of meridians, occasioning a double set of corners on those lines, which are designated as "standard corners" and "closing corners." In rugged mountain regions it has been found

* From Copp's Land Owner.

necessary to depart somewhat from the regular system of extending the standard lines, owing to the impracticablility of surveying them in place. Under these circumstances the principal lines are run and marked in localities admitting of the extension, by means of offsets on township lines, marking them as such in the field.

To be continued.

PERSONAL.

P. H. Dudley, C. E., the inventor of the Dynagraph, is now in Chicago for a few days and letters to him may be addressed to office of ENGINEERING NEWS.

CORRESPONDENCE.

FORT WAYNE, *Jan. 19th, 1877.*

Editor ENGINEERING NEWS:

SIR—In your publication of my letter of the 4th inst., the sine is omitted in the second formula, on the 39th line; D S is used instead of V S on the 40th line; S is also omitted on the 46th line—be kind enough to make some little note of this.

JOHN RYALL,
City Civil Engineer.

WITCH HAZEL.

Editor ENGINEERING NEWS:

SIR:—Although the witch hazel will not turn in my hands without an effort on my part, yet I can follow a "water witch" around, and make the hazel do just what he does, and not be detected by the bystanders; and still I do not feel justified in doubting the word of a "water-witch" whom I have found to be honorable and trustworthy in all other matters. B. F. D.

BOWDOIN COLLEGE, BRUNSWICK, ME. }
Jan. 17th, 1877. }

Editor ENGINEERING NEWS:

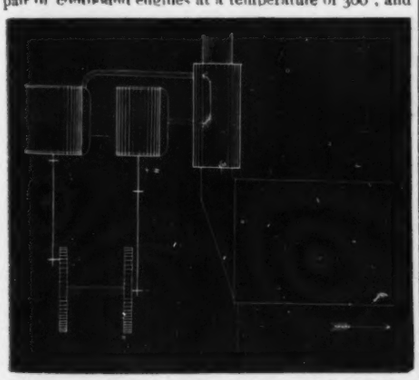
SIR:—I wish to add my opinion to those you have already received in regard to the great value of your paper. I find it an excellent thing for my engineering students to examine, week by week, as it not only contains solid articles of great value, but also many hints and suggestions which furnish them with much food for thought, and awaken much lively interest in the classes, inducing them to study many points which might otherwise escape their notice. Wishing you the success which your efforts deserve.

I remain, very respectfully
GEORGE L. VOSE.

KANSAS CITY, *Jan. 15th, 1877.*

EDITOR ENGINEERING NEWS:

SIR:—Among the many studies for economy of heat in steam engines, there is one that I have not yet seen discussed, although it may not be new or uninvestigated. I can present it more easily in the form of a question. Hot gases from combustion leave a boiler carrying, say 65 or 70 lbs. absolute pressure, at a temperature of say 312°, and escape into the chimney at this temperature; we will suppose that steam is admitted to the smaller of a pair of compound engines at a temperature of 300°, and



is reduced by expansion in the larger to 200°; now here is a loss of 100° of temperature. Why not decrease this loss by returning the exhaust steam to a proper superheater, as shown in the accompanying sketch? Will it not avoid at least a portion of the loss due to conduction and condensation, besides receiving an actual increment of power from this otherwise unutilized heat—at the same time without risk of overheating the machinery? Another question. Why not utilize this heat to surround the cylinder, instead of a live steam jacket, the condensation in which is absolute loss?

I would be glad to learn from competent authority, whether reliable economy is not practible in this manner, and if it is, how much can be expected? G. W. P.

KANSAS CITY, MO., *Jan. 23d, 1877.*

Editor ENGINEERING NEWS:

SIR:—Problem by X, pp. 20, current volume. Have had a similar experience and been perfectly successful.

The question is not friction, though with a rise of 25 feet in 750, there being but about 5 feet of head left to act on, the flow will be necessarily small. The success of a pump under such conditions depends on three essentials: first, that the construction of the pump is such as to have no lurking places for air; a minute amount of air collecting in the pump and not perfectly expelled at each stroke will inevitably cause failure. So will a valve having a small opening compared with the surface bearing on the seat; an easy lifting valve being the second essential. The most important of all is a proper consideration of the *inertia* of the moving water. No ordinary pump will overcome this in a long line of pipe if it works simply by ordinary single stroke, for that requires that the column of water be repeatedly stopped and started. Adequate means must be provided to make the flow of water in the long line continuous. This can be most easily done by a vacuum chamber attached to the suction pipe near the pump, and rising somewhat above it; the attenuated air in this permits water to flow into it during the down stroke of the pump, and thus makes the flow in the long line continuous. The importance of a proper vacuum chamber is not so generally understood by mechanics as that of the air-chamber above the pumps—which in many cases is of much less importance.

G. W. PEARSONS.

NEW LONDON, WIS., *Jan. 4th, 1877.*

EDITOR ENGINEERING NEWS:

SIR:—Allow me to disagree with your reply to "H," Nov. 25, 1876. I think a surveyor should *never* adopt a principle of expediency; and so would accept the last three lines of your advice to "H," first. If "H" desires to know what the courts will decide, he is respectfully and modestly, but very confidently, referred to page 79 of ENGINEERING NEWS for 1875, reading "portions of land," instead of "positions of land."

No man is obliged to abide by the decisions of a county surveyor, or city surveyor, or any other surveyor. If he is not satisfied with the survey of his land, he must take his case into the court. It is the surveyor's duty, and it is within his power, to so understand the law and his business, that the higher courts will always confirm his decision,

If I were surveying under such circumstances as "H" mentions, I should pay no more attention to the lines already run (except government lines), than if there had never been any run.

The sooner people find out the difference between a competent surveyor and a pretender, the better it will be for everybody except the pretenders. B. F. D.

CANTON, ILL., *Jan. 22d, 1877.*

Editor ENGINEERING NEWS.

SIR:—I wish to make some statements relative to two very interesting articles in your issues of Nov. 18th and 25th, 1876, on the "Improvement of the Lower or Des Moines Rapids of the Mississippi River," by E. Hudson Worrall, U. S. Engineer. The original plans and estimates for this work were made by D. C. Jenne, C. E. (now chief engineer of the Illinois River Improvement), under direction of Gen. J. H. Wilson, and I have his authority for this article.

In the second column of the issue of Nov. 18, Mr. Worrall quotes from Gen Wilson's report of Jan. 1st, 1869, giving the dimensions of the proposed canal and the cut in the channel at Montrose. He then speaks of a report made by a "Board of Engineers," recommending certain changes in the details of this plan, and that the recommendations were concurred by the Chief of Engineers and approved by the Secretary of War, and that the work was estimated to cost $3,390,000.

By reference to the report spoken of, it will be found that this amount contemplated the largest sized canal—one 300 feet wide 6 feet deep, with a river bank 20 feet wide on top, and built 4 feet above high water, and a channel in the river at Montrose 200 feet wide and 6 feet deep at low water. Four different estimates were made (found on pages 285 and 286 report for 1867), with the total cost as follows:

1st. For a canal 300 ft. wide and 6 ft. deep, with a channel at Montrose 6 ft. deep. $3,390,000
2d. For a canal 300 ft. wide in embankment, 200 in excavation, and 6 ft. deep, channel at Montrose the same..... 3,110,000
3d. For a canal 300 ft. wide, 5 ft. deep, and a channel at Montrose 5 feet deep..... 2,290,000
4th. For a canal 300 ft. wide in embankment, 200 in excavation, 5 ft. deep, channel at Montrose 5 ft. deep..... 2,710,000

The Board of Engineers referred to in their report gave the total estimated cost on the plan recommended and adopted as $2,530,000 (pages 340, 341 and 342 Chief of Engineer's Report for 1867); this amount is $360,000 less than the amount stated by Mr. Worrall. He states the total cost of the work will be $4 281,000, this is $1,751,000 above the estimate of the Board of Engineers, an increase in cost of 69 1-5 per cent.

Mr. Worrall does not credit any sluices around the locks as being contemplated in the original plans, and says from some unaccountable reason they were overlooked, and that their construction increased the cost. On page 284, report for 1867, special reference is made of the necessity of sluices around the lift locks, and reference is made of their cost being included in the estimate. CHAS. LEVINGS, C. E.

BOOK NOTICE.

FORMULÆ FOR R. R. EARTHWORK, By J. W. Davis. New York: 1876.

This little book is very comprehensive and satisfactory, so far as the theory is concerned at least. The author has carried out his idea of reducing all calculations to one systematic process, and has extended the application of his system apparently to all the cases which arise in actual practice. The *accurate formula* for the contents of a volume is so transposed as to reduce the operations and the sizes of the numbers to be dealt with as much as possible, and one is enabled to calculate the entire contents of a cut or fill, except the small end volumes, at one operation, no matter how many plus stations may be taken. This method possesses the further advantage of using the field notes, exactly as taken. This small volume has been adopted as a text-book at the School of Mines, Columbia College, and is apparently issued under the sanction of that department.

We should be glad to see exact methods, such as the one before us, taking the place of the approximate rules and some of the poor tables which are sometimes used. But we are afraid that the *average section engineer*, who usually has these computations to make, will at first sight, consider this method too complicated and so lay it aside. There is something here left to judgment and discretion in taking field notes, and a method which follows an arbitrary rule, is apt to be better liked.

The author has, perhaps, magnified the importance of his task, as if the computation of earthwork were largely the end of an engineer, in which business an economy of time was of great importance, and takes up considerable space in vindicating the merits of his system over others, although he compares his with the more antiquated, and generally acknowledged imperfect, methods, rather than with the later results of Wellington and others. He does not have so good an opinion of the accuracy of diagrams as we have been led to entertain from our own experience. We cannot speak as well of the mechanical execution of the book as of the matter contained in its covers.

In conclusion we would say that the book is well worth the careful perusal of any engineer who is engaged in such work.

Celestial Dynamics, A new Theory with, Discoveries in Astronomy. By Rev. Jas. W. Hanna. Mt. Vernon, Iowa.

In this little pamphlet of 32 pages, the reverend

author has slain Galileo, demolished Kepler, and utterly annihilated poor old Isaac Newton, who it seems did'nt know much about astronomy after all. In the spring of 1876 he confesses that he himself knew very little about astronomy, but by the time of his July vacation he had the "new heavens and the new earth" pretty well organized, when he proceeded to submit his conclusions to Prof. Newcomb of the Washington Observatory, who, however did'nt accept the new theory very readily, when the author proceded at once to that celebrated astronomer, President Grant, who being very busily engaged at the time in some terrestrial observations of his own, referred the author of "Celestial Dynamics" to the "Professors in the colleges." As we are not now prepared to give up the old-fashioned idea of the planets revolving around the sun, and a few other simple theories about the movements of the heavenly bodies, which we learned in years gone by, we must also leave the further consideration of the subject to the author and the "Professors in the colleges." But it is worth the small sum of thirty cents to become acquainted with the new theory, and that is all that is asked.

PRACTICAL TREATISE ON THE CONSTRUCTION OF IRON HIGHWAY BRIDGES for the Use of Town Committees, together with a short Essay upon the Application of the Principles of the Lever to a ready Analysis of the Strains upon the more customary Forms of Beams and Trusses. Alfred P. Boller, A. M. C. E., Member of the American Society of Civil Engineers. New York. 1876. Chicago: Geo. H. Frost. Price, $2.50.

The writer dedicates his book to "Town Committees, Selectmen, County Freeholders, and other public officers to whom is entrusted the responsibility of erecting Iron Bridges;" and in telling them what are the essential elements of a good bridge, he supplies them with a large amount of practical information that has hitherto been inaccessible to them. If he does not succeed in gaining their attention, it will not be for a lack of merit in his work. In undertaking to educate the average committeeman or Freeholder, Mr Boller has addressed himself to a Herculean task; these gentlemen will continue to build as cheaply as the law will permit, and stringent laws alone will prevent the erection of unsafe highway bridges.

The author must be content with having produced a book which is very valuable and useful to the general engineer and to the young bridge engineer about entering upon the practice of his profession. If the former is not an expert in this branch of engineering, he will find here written in a compact, clear, straightforward manner, exactly the hints and information he needs when suddenly called upon to examine bridge plans and specifications, or to act as inspector of bridges; the latter will look in vain in his text books for the practical knowledge that is here conveyed, and that is so necessary to him.

The distinctive physical properties of iron are fully pointed out, the qualities it should possess, and the tests to which it should be submitted, are described so that the inexperienced may judge; then, after a few words of sound advice about timber, the author describes the different kind of bridges in general use, and in regard to the selection of a plan gives this advice, which is good for engineers as well as committeemen: "Ignore any plan of bridge that cannot be accurately analyzed as to the character and amount of strain occurring in all its parts."

There are some very sensible and timely remarks upon connections and upon the merits of the two systems of bridge building—the American and the European—showing how the former so greatly excels the latter, and why it has attained the noble position of being the best system, scientifically and practically, in the world. Struts or posts, eyes and eye-bars, pins and rivets with their sections, sizes and proportions, are fully treated of; while loads, roadways, sidewalks, pavements, in fact, everything pertaining to a highway bridge receives proper attention. Neither do the æsthetics of bridge construction fail of their share of consideration.

The second part of the book is devoted to the consideration of strains in girders and simple trusses, and very simple methods are given for finding them in the ordinary forms in use.

Altogether, the author has more than well fulfilled the task he allotted to himself, and given a large amount of valuable practical information obtainable from no other source.—*Journal of American Society of Civil Engineers.*

NOTES.

Frozen fire-plugs were the indirect cause of a $30,000 fire in Lancaster, Pa.

The fire in the mine near Lykens, Pa., is under control, and the damage is not so great as was thought.

At South Sugarloaf, near Hazleton, Pa., Messrs. A. Pardee & Co., have, after considerable prospecting, struck a new vein of coal ten feet thick.

The Wilkesbarre Coal and Iron Company has just taken a twelve years' lease of a large wharf at New Haven, Conn., and will build a great coal depot there.

At South Bethlehem the Bessemer Steel Works are running with full force on orders which will keep them busy until next spring. Their rail and merchant iron department is but moderately engaged. The brass works, the shovel works and all the lesser manufacturing concerns at Bethlehem are moderately busy.

Directions have been issued by the British Admiralty for the use of slaked lime for the preservation of those portions of the framework of iron vessels which are constantly exposed to the action of salt water. It is to be placed on the iron frames, and in the water contained in such compartments, bilges and wings, as cannot be dried out sufficiently to allow the application of preservative paints.

Steps have been taken to acclimatize the Florida cedar in Bavaria. The superiority of the wood of this tree over all other kinds of cedar is well known, and the demand for the species in Bavaria, where immense quantities of lead pencils are made, has induced manufacturers to venture on the experiment. Seeds have been sown in the royal forest, and about 5,000 young plants are now thriving in one batch.

Captain Eads, in charge of the jetty works at the mouth of the Mississippi, has been awarded the first payment on his contract, amounting to $500,000.

The Maryland and Virginia boundary arbitrators are delayed in making their award, mainly by their differences as to the line to be run from the southern terminus of the Potomac river boundary to the Atlantic ocean.

The question of miners' wages is still in agitation in the Cumberland, Md., coal region. The Consolidation, New Central and Franklin companies have reduced the price of mining from 65 to 50 cents per ton, and other companies are considering the matter. Several meetings of miners have been held, but no definite conclusion has been reached by them.

Public improvements in the city of Washington are entirely suspended, and whether or not there will be any made during 1877 depends on the action of Congress. The field force of the city engineer's office was reduced on the 15th of the month.

The contractors, Messrs. Carpenter and Colbath, having failed to complete the Marshalltown, Iowa, Water-works, according to contract, the city, on Jan. 6th, took possession of the works, and will go on and complete them at the expense of the contractors.

Upon information of Peter Cain, state inspector of mines for Alleghany and Garrett counties, the Maryland and George's Creek coal companies have been indicted under the act of Assembly of 1876, providing for the ventilation of mines and protection of miners, for alleged refusal to furnish at their own expense sufficient "props" for the protection of the miners in their respective works. The law is a very stringent one, and its provisions will be tested in the trial of this case, which, for that reason, will be of great interest.—*Cumberland News.*

A paper upon the currents at mouths of rivers, remarks that where these fall into the sea, an under-current of perfectly salt water, according to the depth, the nature of the bottom, etc., runs up to a quarter or less distance in the opposite direction. The Gotha for instance, half a (Swedish) mile before its entrance into the sea, has water at the depth of two fathoms of almost the same saltness as sea-water at a similar depth, a mile and three-quarters from its mouth. Currents in general are caused not only by the difference in specific gravity, but also by the distribution of rainfall, evaporation, heat, etc., which produce surface changes.—*Harper's Weekly, Jan. 27.*

NOTES AND SUGGESTIONS ON THE CROTON WATER WORKS AND SUPPLY, FOR THE FUTURE.*

BY BENJAMIN S. CHURCH, C. E.

NOTE.—The following comments are not intended to detract from the merits of one of the greatest achievements of modern engineering, or in anywise to underrate the masterly ability displayed and remarkable success achieved, in the plans and construction of the Croton Aqueduct. The wonder is, that so few oversights occurred to challenge criticism, and now, after the lapse of over thirty years, these suggestions are simply offered to carry forward to fuller perfection, the work as it at present stands.

PRELIMINARY.

The Croton Aqueduct is constructed of hydraulic cement masonry and lined inside with brick. The sketch given below shows in section the general form, which is slightly varied in earth and rock tunnels.

The maximum grade of the aqueduct is 1.1088 feet per mile, with the following variations, viz.: at Croton dam, where for 5 miles the fall or grade is about 7 inches per mile; at High Bridge and Manhattan valley, where the water is conducted across in pipes, and a slightly increased fall given to overcome friction, and from Manhattan valley to the reservoir in Central Park, a distance of 2 miles, where the grade is 9 inches to the mile. A considerable portion in crossing streams and ravines, about 5 miles in the aggregate, rests on rubble stone foundations, built up without mortar, and upon these one foot of hydraulic concrete was laid, forming the grade plane sustaining the aqueduct structure. Entirely covering this and its foundations, are earth embankments with outside sloping walls, the object being protection from frost, also to assist in balancing water pressure in the aqueduct.

Now, on all these embankments, one hundred and twenty-five in number, varying from 100 to 14,000 feet in length, and from 10 to 40 feet in height, the masonry enclosing the column of water has not proved of sufficient strength to resist lateral hydraulic pressure of full water flow, and the friction from minute but constant movement always existing in dry foundations. In some places, these foundations have settled and disturbed the even bed of support of the aqueduct, especially as the tendency of this settlement is to spread the wall; consequently, on all these embankments between Croton dam and the city, the aqueduct has split longitudinally through top and bottom, being torn asunder by the above mentioned forces, causing leaks of more or less serious nature. Some of these leaks during a sudden and severe change of weather become so alarming as to make it necessary to shut off the water at Croton dam and empty the aqueduct for repairs, which can only be made inside. Whenever a leak occurs, be it near the upper or lower ends, the entire aqueduct must be emptied. This is necessitated from the fact that waste gate-houses 6 or 8 miles apart, are not provided with cross-gates to enable the water to be stopped at that point and turned out. When such a serious leak occurs—which has been the case on a certain embankment within a few miles of High Bridge—it requires thirty hours to rid the aqueduct of water, in order to repair, and fifteen hours more for the water to reach that point again after being turned on at Croton dam; thus making a loss of forty-five hours, exclusive of the time taken for repairs, when three hours would suffice were there cross-gates as above suggested.

These forty-five hours involve the loss of 220,000,000 gallons to the city in that space of time. The want of strength on these embankments has become more apparent because of the rapidly increasing use of water demanding greater depth of flow in the aqueduct, which entails corresponding increase of lateral pressure, tending to reopen fissures that have been repaired. The outside protection walls have been raised and strengthened, and the embankments more thoroughly drained, which, to a certain degree, has prevented the further settlement of foundations and put the aqueduct in somewhat stronger condition than in former years, to sustain its increased burden. A thorough renewal of the broken parts would, however, require a longer stoppage of water supply than the city storage now allows; therefore, repairs heretofore made, although the best that conditions permitted, have been temporary and imperfect. Had the bottom of the aqueduct, instead of being

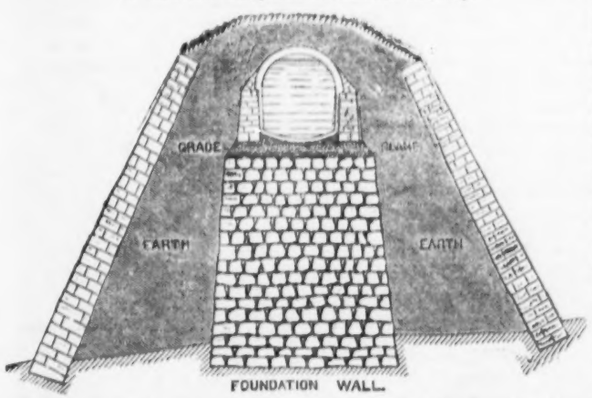
*A paper read before the American Society of Civil Engineers, February, 1876.

formed of 15 inches of concrete and 4 inches of brick, been made 3 feet thick of solid masonry lined with 4 inches of brick and correspondingly increased thickness of side walls, these longitudinal ruptures would hardly have occurred, as therein would have been contained requisite strength on embankments where alone the aqueduct has proved weak.

For some years past the constancy of supply has been maintained by the following expedients, viz.: so soon as a leak appears, sawdust, fine sand or loam mixed with water into a paste, is prepared and dumped into the aqueduct at an opening above the leak and carried down by the current and drawn into the fissures, when it swells and chokes the leak temporarily until some change of temperature or water pressure loosens it, when the process is repeated. By this means, leakage being kept out of these foundations, the movement is much checked, which frequently obviates the necessity of shutting off the water for inside repairs, unquestionably resulting in distress to the city. Increasing vigilance and care have been required on the part of the engineers and their employees to keep up the daily supply.

The city consumption has so nearly reached the carrying powers of the aqueduct, that it can but slowly refill the reservoirs when drawn down. Stoppage occurring for inside repairs, which occupy three days and nights, draws the water down 8 or 10 feet; and this amount of pressure taken from service pipes, is a loss sufficient to deprive upper stories of water, over a considerable area of the city. Under present conditions, should an immediate succession of repairs, such as have occurred, become necessary, the reservoirs would be so reduced that consequences might be disastrous.

A CROTON ACQUEDUCT EMBANKMENT,



In the plans of the reservoir gate-houses, an important change could be made which would relieve the present embarrassment in making repairs, and better regulate city supply immediately following. It should be borne in mind that a full reservoir is now necessary to give full pressure to the city, its high water line being on a level with the top of the aqueduct. The present gate-houses are arranged for the aqueduct to deliver into the reservoir basins, and the main pipes conveying water to the city are supplied from these basins only. Hence every foot lost in the reservoirs is taken from pipe service pressure, only to be regained by refilling the reservoirs. The inconvenience occasioned by this could be obviated by constructing waterways with gates arranged to enable the water to be turned into them directly from the aqueduct and fill to full height the gate house chambers supplying the main pipes. Turning on full water head after repairs, would thus insure its immediate pressure throughout the city, and the surplus beyond city consumption could flow over weirs, and slowly refill the reservoirs at exactly the present ratio. By this means the city could be supplied directly from either the aqueduct or reservoirs as occasion required, and a much larger amount of storage made available. If the city used all the conduit could furnish, this arrangement would, of course, be inoperative, but that need not, and ought not to be, when means are at hand to prevent, as suggested further on.

PIPE DISTRIBUTION.

Comparatively uniform distribution of water can be as readily insured to large as small cities, if they are divided into districts, each district mapped in reference to altitude and provided with a main proportioned to its area. These mains must be so arranged that by opening connecting gates, water can be turned from one to another when occasion requires, either for relaying, repairing pipes, or to increase supply for fire.

When Croton water was first introduced, the mains laid were larger than necessary at the period, and the supply of water so abundant that a very general plan of distribution sufficed. Under present conditions, but small attention has been given to separating the circulation of localities differing in elevation, hence the cause of unequal supply. The growth of Now York has been scattered and irregular, and the power to order pipes laid for newly built localities was formerly in the jurisdiction of the Board of Aldermen. Small street service pipes were connected here and there with the nearest mains, without reference to a well planned system, and it has resulted in a most complicated network of pipe connections delivering without uniform pressure and difficult of control.

Reiterating the statement that the city is consuming nearly the maximum supply of the aqueduct, the question arises how to provide for the present and immediate future? The city average steadily increases, and there is no possibility of increase by the present aqueduct. It is true the falling of the reservoir regulates, in some degree, the use of water by diminishing the pressure, as previously stated; but this diminution is attended by evils that deserve serious consideration. The stoppage of flow in upperstories is, in a sanitary point of view, disastrous. On floors where hand basins and closet traps are apt to be deprived of water direct communication with the sewers is established through drain pipes. These pipes act as chimneys to draw up the poisonous gases, productive of diphtheria, typhoid and otherfevers; or should the same water remain for any length of time in the traps of basins and closets, it becomes charged with these gases and transmits them to rooms to breed pestilence. The difficulty in obtaining full pressure in case of fire, with all the attendant danger and pecuniary loss, need not be enlarged upon.

The true alternative to counteract the evils enumerated is to stop the abuse of the water privilege. An unreasoning impression seems universal among our citizens that water should be free as air and sunlight; but they are oblivious of the fact that Croton water embodies a vast amount of treasure—costing the citizens of New York $6,000 per day, or ov r $2,0 0,000 yearly.

To prevent waste, furnishes the only solution of this problem. Even after the construction of a new aqueduct, a matter of four or five years, which necessitates increased pipe service circulation to deliver the increased supply, the growing habit of reckless waste on each individual in a population constantly enlarging, is like a disease beyond the power of any but temporary remedies, and future years would undoubtedly exhibit a recurrence of present troubles if this habit be not checked.

It is generally supposed that the increased consumption of water has arisen from growing manufacturing interests, and the pumping of water to supply buildings in the lower business portion of the city, which now contains structures double the height of former years. But business houses and manufactories are closed on Sunday, with few exceptions, and use little or no water; yet the reservoirs gain on that day only 6,000,000 gallons, or thereabouts, which is a marked indication that it is in dwelling places and private residences, the principal waste occurs.

Standard authorities have fixed the following data, as a basis for estimating the quantity of water required for abundant supply of cities and towns—minimum 20, and maximum 40 gallons, per head per day. A large estimate of the inhabitants of New York, including transient visitors and people living out of the city, but transacting business within its limits, is 1,100,000 persons; whence the maximum supply would be 44,000,000, and the minimum, 22,000,000 gallons per day. Now the average daily consumption of New York is 114,000,000 gallons, which is more than two and one half times the maximum, and five times the minimum supply, which should amply suffice. The city of London, containing three times the number of inhabitants of New York, daily uses 100,000,000 gallons, thus verifying the above estimate.

With us, there is absolutely no check upon reckless consumption, save in the single instance of steam boilers. These are rated by horse power; yet the establishment using the boiler, may waste at discretion elsewhere through the building, and often much more is used or wasted than is required for the engine, with no possibility (without meters) of measurement or discovery by the authorities.

When the temperature becomes suddenly cold, the water is set running in every house to prevent pipes freezing, turning into the sewers nine or ten millions of gallons and drawing down the reservoirs 3 inches in a night, to recover which, requires three days of mild weather. This amounts to forcing the city government to protect private plumbing, aside from bringing possible danger and disaster back upon households, in robbing upper stories and creating a short supply in case of fire. There are other sources of waste—such as drawing more water than the occasion demands—of themselves insignificant, but multiplied by thousands of similar instances, they assume formidable proportions. Tanks are often so arranged that after being filled at night, when the pressure comes, the water goes on running because no float valve is furnished to stop the flow, and this not only in dwellings, but in factories and wherever water is used in large or small quaantities.

Were each consumer compelled to pay proportionately to consumption, a less expensive method then letting water run would be devised for protecting plumbing. The house main connecting with the street would be laid below the reach of frost, and pipes carried up in the interior, instead of against outside walls, where plumbers, in their own interest, prefer to place them; or they would b encased in charcoal, sawdust, plaster of Paris or any non-conductor; self-closing faucets would be used, causing the water to cease running when the hand is removed. Owners of docks, sugar houses, manufactories, and other places of large consumption, would immediately resort to similar devices to prevent carelessness which would result in personal expense.

The effect of preventing this enormous waste, which (aside from a large percentage for leakage in street pipe service) is estimated to be fully double the amount of water required for use, becomes important because of another law involved than that relating to pressure from a full reservoir. It is the law concerning "the flow of water in pipes under uniform head, viz.: velocity and pressure become interchangeable terms; as velocity increases, pressure diminishes, until it disappears in velocity, and vice versa." Thus velocity being checked, pressure is regained.

In the application of this law, stoppage of waste, (equaling say one-half the supply) diminishes velocity one-half, thus doubling the average pressure throughout the city. The relief of the aqueduct of excessive strain which it now sustains without intermission, dangerously increasing its liability to rupture and leakage, should not be lost sight of in this connection.

Unquestionably the universal adoption of meters by the city is the simplest and easiest method of obviating the difficulties and dangers above enumerated. Meters should be considered in relation to their influence on the water supply as reducing the load carried by the aqueduct and in keeping the reservoirs filled, diminishing velocity of flow in the pipes by checking waste, thereby giving ampler pressure through the city. It is a mistake to view them only as of interest to inventors and speculators, or from the stand-point of increased revenue from water payments which have always accrued from their introduction. Although of great relative importance, the paramount urgency for immediate measures to counteract the present unsafe condition of our water supply should outweigh minor considerations of unreasonable prejudice against their use.

There are various meters existing, to meet every difference of requirement, either for large or small consumption, high or low pressure. Water can be measured by meters with more accuracy than gas, which is compressible. A cubic foot of gas represents more or less according to the pressure brought to bear, while no amount of pressure will sensibly alter the bulk of water. If gas consumers neglect to turn off a high pressure in the cellar, a third more gas may be allowed to flow through burners than is necessary to give the same or even better light. With water this variation is not possible, the meter being far more reliable and honest.

It is urged that payment for water by measurement might lead in some cases to uncleanly, penurious and unhealthy economy. To prevent this, a law providing liberal amount for dwellings according to their size, can rate taxation by the present system. But, beyond this allowance for legitimate use full charge should be made per cubic foot. Having to pay regularly for sufficient amount, whether used or not, no advantage would be gained from mean economy, while waste would involve a pecuniary responsibility. The cost of metering the city would amount to between two or three million dollars, but it would be refunded the city within a few years by increasing the water revenue.

If this method of preventing waste be not resorted to, the only alternative would be to procure an additional supply of water by the construction of a new aquedect. That a new aqueduct, separately located, and independent of the present one, will be ultimately necessary, seems unquestionable. The present aqueduct has been strengthened to the utmost, of late years, but the increased load it is called upon to carry, as before stated, renders it liable to a succession of mishaps such as have formerly occurred, at a time when the situation was far less critical than now, in which event water famine would inevitably result. The city of New York can well afford and should take immediate steps to protect itself from such possible calamity. During the storms of last July, when the Hudson River Railroad and Albany Post Road were rendered impassible, land slides occurred on the aqueduct between Tarrytown and Sing Sing, and had the fury of the storm struck one of three places above, a portion of it might have been seriously damaged. In 1865, during a similar storm, the rush of water carrying debris, choked the culvert under a high embankment, which was cleared at great risk of life, only in time to prevent water damming to the height of 30 feet against the aqueduct, to the immediate danger of the structure.

From the foregoing statements it is evident that action is imperative to provide for emergencies which, if not yet upon us, are none the less threatening. Meters should be applied, or a new aqueduct constructed without delay; the former appears to be the cheapest and most available resource, while the latter must ultimately be resorted to, and fortunately the Croton river offers unlimited supply for all future demands.

A thorough survey of the Mississippi river is to be made from Cairo to New Orleans. Efficient engineers are in charge and careful observations will be made in regard to the wear of the river's bed, the best sites for the construction of levees and whatsoever may come within the scope of the enterprise.

ARCHES;

CONSIDERED GRAPHICALLY.

[Copyright 1877.]

(*Continued from page 22.*)

A curve may first be drawn tentatively, ordinates be measured at intervals, and the above products computed. It will then be readily seen whether the curve should be moved up or down; to move it, change H, and draw again. We can deal thus with a rib of any outline, but, for the regular forms of arches commonly in use, we will show presently how to determine the exact curve of equilibrium without experimental trial.

12. The vertical component R S, of the displacement B R, manifests itself, since B does not move, by a slight movement of the rib at E vertically, corresponding to the deflection of a beam under transverse forces.

13. It has been shown that H. E F equals the bending moment at E. If we draw from E a perpendicnlar E N, to that side of the curve of equilibrium which passes through F, the side being prolonged, if necessary, we shall form a right-angled triangle, similar to one in the stress diagram formed by H, the line parallel to the side of the polygon, and the vertical line. Thus, in the figure, the triangle E F N will be similar to 025, and we may write the proportion

$$0\text{-}2 : 0\text{-}5 = E\,F : E\,N;$$

or, if T denotes the tension 0-2 in the part of the cord which passes through F, multiplying extremes and means, we get

$$H.\,E\,F = T.\,E\,N; \qquad (5.)$$

so that the bending moment at each point is also equal to the product of the tension in the cord by the perpendicular let fall on the cord from the given point. The discussion of the bending moment might have been approached in this way.

14. If a force T acts in the line A K, which, when we consider the curved rib, in an imaginary line, its moment with respect to the rib at E is plainly T. EN, as shown above. Now, from mechanics, if we analyze the effect of a force T at any distance laterally from a point E, we may apply two equal and opposite forces, + T and—T, at this point, which is here the middle of the rib, Fig. 3, or what would be, for flexure only, the neutral axis, without destroying the equilibrium. Hence we have at E the direct force +

T, producing tension, and the couple T. EN, producing flexure. The enlarged sketch will represent the condition of the rib. The small arrows at E′, denote the magnitudes or intensities of the stresses which form the moment of resistance to balance the bending moment, these intensities being taken as uniformly varying, a supposition which is satisfied by experiment within the elastic limit; at E′′ are shown the stresses on the particles of the section from the direct force; and the combination of the force and moment is represented at E′′′, it being understood that these several views represent one and the same section E. The point of no stress, or the position of the neutral axis, is seen to be shifted from the middle of the section at E′ to one side at E′′′, and it will disappear altogether when the arm of the couple or moment becomes sufficiently small, so that the entire section may be under one kind of stress of varying intensity. If we know the form of cross-section of the rib, we can tell from the location of the curve of equilibrium, by simple inspection, where we shall find both tension and compression, and where only one kind of stress. This matter will be treated of later.

15. It is not probable that the direction of T will be parallel to the tangent to the curve of the rib at the particular point, but, when not parallel, the direct force in the rib is in the direction of the tangent, and is greater than T, in just the way that a vertical or horizontal force, when transmitted through an inclined member, as, for instance, the rafter of a roof truss, gives rise to a greater stress in that member. In any case, therefore, the direct force in the arch at any point will be the amount which in horizontal projection will equal H; or, in other words, to find the direct force in the arch, multiply H by the secant of the inclination of the centre line of the rib at that point to the horizon.

16. When an arch is under analysis all the figures which have thus far been given will be inverted. Imagine them to be so. All of the forces will then be *reversed*. The polygon which was under tension will be compressed, and its sides will therefore be struts. It will be in unstable equilibrium, and, not being so familiar to us, is not perhaps so readily apprehended, in its relation to vertical forces, by one not acquainted with this subject. For this reason it was thought best to take an inverted arch first. Hereafter the arches will be drawn above the springing line.

17. The curved rib, between the points A and C, so long as there is tension along the straight line A C, tends to move towards that line, just as the cord, if drawn towards the arch, returns to its former position; but, as soon as the figure is inverted, and C is forced by compression towards A, the arch tends to *move away from the curve* of equilibrium. This fact is true of all points of the rib and must be borne in mind. All the bending moments are therefore reversed. The arch is also under direct compression and tends to force apart the abutments.

It may help to fix the ideas to take a piece of steel wire, such as hoop-skirt wire, bend it into the arc of a circle, and, placing the two ends in two notches upon a board, to notice the change of shape arising from a pressure or load imposed on any portion. The movement of the wire will indicate, in a general way, where the curve of equilibrium lies in reference to the rib.

18. It will be readily seen that the curve of equilibrium for a single, concentrated load on an arch is composed of two straight lines which meet on the vertical drawn through the point where the load is imposed. In the case just treated, these lines will start from the two springing points of the arch. The only quantity needful to fix their position will be the distance of the point of intersection vertically from the rib, and the single condition of § 11, that $\Sigma\, E\, F. D\, E = 0$, is manifestly enough to determine the unknown quantity. It will be easier to find the effect of a single load at successive points on the arch, and to combine these effects for any possible arrangements and intensities of load, than to treat at once several loads. We shall pursue this method.

19. Since an arched rib is often composed of two flanges and a web or connecting bracing, similar to a girder or truss, we desire, after we have found the bending moments at all points, to find that portion of the vertical force or the shear at each section which must be resisted by the web members. If we make a vertical cross-section of a beam at any point and compute the algebraic sum or the resultant of all the external forces on either side of the section, we shall find a certain resultant on one side of the section, and an equal resultant, but with an opposite sign, on the other side of the section. This must be true, for the two equal and opposite forces, applied at the same point, give the equilibrium which is known to exist. But, if the beam were really cut off at this point, these two equal resultants, from forces on opposite sides of the plane of section, would carry the two parts of the beam past one another, as if sheared off mechanically. Hence the propriety of the term *shear*. It is specially the function of the braces or the web of a girder to resist the shearing forces, and hence we ascertain the shear at all points in order to rightly determine the sections of the braces.

In a horizontal beam, carried on two supports, we should have, in Fig. 2, P_2 for the supporting force, and shear on the right of any section between B and W_1; $P_2 - W_1$, or (1-5)—(3-1), for the shear anywhere between W_1 and W_2; $P_2 - W_1 - W_2$, or (3-5)—(4-3), that is—(5-4), between W_2 and W_3; and so on, subtracting each weight from the previous shear or resultant. But in a beam, or a truss with horizontal chords, the other forces, which oppose the bending moment, are horizontal; here they are not. Supposing the rib to have been inverted, the direct thrust, being in the direction of a tangent at the centre line of the rib, has a vertical component which affects the amount of shear to be resisted by the web.

For notice the location of the curve of equilibrium at B. The two components of the stress along G B are H and P_2. If a sufficient amount of P_2 is combined with H to give a resultant coinciding with the tangent to the arch at the point B, that portion of P_2 is all that can come to B in the direct stress exerted by the rib, while the remainder must come as a vertical component of the web stress or as a shear. If G B lies within the tangent, the same reasoning will hold good, but the shear for the web will be of the opposite sign, or a negative quantity, if the first was positive. The end A furnishes such an example. In short, the inclined flanges or chords act as braces, and we have, at any section, these chords as well as the web members, among which to distribute the shearing force. The action corresponds with that of the bow in a bowstring girder.

20. If then we select a point U on the rib, between the weights W_1 and W_2, we may draw the line 0-6 in the stress diagram, parallel to the tangent to the rib at that point, and 0-6 will be the direct force at U. The shear, for a beam, would have been, at that point, (1-5)—(3-1) or 3-5; but 0-6 is composed of 6-5 and 5-0; therefore 6-5 deducted from 3-5 leaves only 3-6 for the amount of shear to be resisted by the web. At the point Q, likewise, we find that the shear, in place of being 2-5, if 0-7 is parallel to the tangent at Q, is (2-5)—(5-7) or — (2-7) to be borne by the web. On passing along the arch from A to and beyond C, if we pass beyond the middle of the span before we pass as much load as is carried at A, the line in the stress diagram which gives the direct stress in the rib will fall below 5, the extremity of P_2, and the amount of shear in the web will be increased by the distance from 5 to the intersection of this line with the load line. It may be seen that the shear which must be carried by the web members is found by taking the distance on the load line included between the extremity of the line of direct force and the end of the weight last passed. A diagram for shear will be constructed when we take up some arches of special forms.

(*To be continued.*)

A BOLD RAILROAD PROJECT.

We find, in the columns of the *American Manufacturer*, some account, from the pen of a correspondent, of a wonderful railroad scheme, which embraces not only a line from San Francisco through Mexico, Central and South America, to Valparaiso and Buenos Ayres, but also one, via Washington Territory, British Columbia and Alaska, to a port on Behring Straits, there to connect by ferry with a proposed road through Kamtschatka, leading indirectly to all parts of Asia and Europe. It is urged that the South American line would open up States which possess all the elements of commercial wealth and offer a fine field for the expansion of American industry. The project was submitted at Philadelphia, this last summer, to the Emperor of Brazil and to his minister to this country, as well as to other ministers from the South American Republics.

The correspondent, above referred to, John A. Lynch of Washington, D. C., states that his project was, to recommend to the several States of Central and South America, the construction of a line of railroad through their respective territories, running north and south, and so arranged that all, united, would form a continuous, direct line from Mexico to Valparaiso, Buenos Ayres, and Rio Janeiro. It is also reported that some of the leading men and capitalists of San Francisco have taken vigorous hold of the scheme.

There is a decided air of plausibility in this project, and it does not seem any more bold and venturesome than did the proposed Pacific railroads before they were undertaken. A cordial harmony of the different governments would, in the course of some years, effect wonders and the whole line, although immensely long, would be pushed forward in sections. However, our neighbor, Mexico, does not offer a very hopeful field for such an undertaking, at the start, and that section would be the first one necessary to be assured. We doubt not that many of the railroad engineers, who have been forced during the past few years to turn their hands to something else, would heartily welcome the inauguration of such an enterprise.

The other project for some reason or other, strikes us as being particularly audacious. Perhaps it is because its advocates propose to brave the rigors and deep snows of winter in such high latitudes and feel able to keep open a line of communication in spite of the climate. That portion of the great route (which they say is distined to connect this continent with Asia and Europe) lying within the domains of Russia has already been surveyed and marked out by Russian Engineers, under the authority of their government—that is, from Moscow, via Orenburg to Pekin, and a port on the Yellow Sea in China; and via Irkoutsk to Nicholaieft, on the Amoor river, and to Ochotsk. Mr. Lynch goes on to say—"For the people of the United States to share in all the advantages to be derived from the completion of such an undertaking, it is necessary for them, through their government, to approach that of Russia, and by treaty lay the foundations for the undertaking simultaneously by both people.

"If the people of the United States will construct a railroad from Washington Territory, connecting there with the Northern Pacific, and through British Columbia and Alaska, to a port on Behring Strait, which is a total length of only about 1,500 miles, there cannot be a doubt but that the Russian government will authorize and encourage the construction of a railroad from Ochotsk, through Kamtschatka to a port on their side of Behring Strait; thus completing a continuous line of railroad from Valparaiso and Buenos Ayres to all Europe and Asia, through the United States."

"In the quiet of his study, our scientist, Professor Henry, whom the learned bodies of all countries delight to honor, has given his consideration to this project, submitted to him by me, and he pronounces it not only feasible, but a work of national importance worthy of the age, and which ought to be carried forward. I have also submitted it to the government of British Columbia, where it has been approved and encouraged, and obtained the promise of all the aid that can be there afforded. I also had it brought before the European geographical convention, held in Paris in May, 1875, where it was warmly approved of by the Russian delegate."

We believe that, where a prospective improvement offers reasonable assurance of being profitable, private capital can be found to embark in the enterprise, and that such undertakings should be pushed through by private means. We are getting too much into the way of applying for a subsidy from the government as a help towards the construction, and then of endeavoring to shirk the obligations of repayment which we took upon ourselves. Railroad projects canal schemes, slack-water navigation, etc., all call for aid from the public purse on the ground of public benefit. If the line of communication is a public benefit, let the public pay for it in tolls of one kind or another, The government will pay for transportation of mails, of troops and of supplies; private freight, or vessels passing through the canal, will be subject to proper charges, and those parties, therefore, who in any way reap the advantage of the improvement, will do their part towards supporting the same. When we are asked to vote government aid towards building a railroad through the rugged and inclement region of Alaska, we shall probably hesitate long before granting it. We presume that grants of alternate sections of public land on each side of the line in that region would hardly induce capitalists to take hold of the enterprise.

THE *Scientific American* makes mention of a "novel method" for removing snow from railroad tracks, invented by a resident of Houghton, Mich. The inventor simply makes use of the same element that piles up these obstructions on railway tracks, to remove the same. Thus a great scoop is placed in front of the locomotive wide enough to clear the whole track at once. Into this the snow is forced by the advancing train, and now, by an artificial blast of air, this mass of snow is instantly raised and forced up through an upright pipe or stack, the top of which is hung on a swivel, which is turned in whatever direction the wind may be blowing. Suppose a train moving at the rate of forty or sixty miles per hour, it is self-evident that the snow would enter the mouth of the scoop at the same rate of speed, but here it would instantly meet with a counter current traveling at the rate of 100 miles per hour, if needed, and this would scatter the snow like chaff before the wind, so effectually, in fact, that not even a pile of snow a foot high would be left within a radius of hundreds of yards from the track.—*Boston Transcript.*

WE agree that this is a "novel method" of removing snow, and it reads as above very neatly. We should be interested, however, in seeing some calculations on the amount of power required to carry up and blow away the snow at the velocity of 100 miles per hour, and at the rate of 40 miles of track per hour. This power we presume is supplied by the locomotive from the surplus which remains after drawing the train at 40 miles.

This inventor runs in the same groove with another Michigan man who sent us for inspection and comment, a project for the cheap conveyance of grain to the seaboard. He proposed to lay down a line of pipe between Chicago and New York, with blowing engines at intervals of a few miles which should create a strong current of air through the tube. Then, as he assumed that any bodies introduced tended towards the centre of the tube so that there would be only the slight friction of air upon the iron, all that remained was to turn in the wheat or corn in a steady stream at Chicago, when it would pass along the axis of the tube, curiously suspended in air, and be delivered at New York with any desired velocity.

At a meeting of the Common Council of New York City January 25th, it was decided, "That the Commissioner of Public Works be requested to report upon the system adopted by the Liverpool Water Board, for the prevention of waste in the use of water and the practicability of applying the same or some similar system to the water pipes in this (N. Y.) city."

A complete description of the system above referred to is given in the paper entitled "On the System of Constant and Intermittent Water Supply, and the Prevention of Waste, with special reference to the restoration of Constant Service in Liverpool." By Geo. Frederick Deacon, M. Inst. C. E., read before the Institution of Civil Engineers, April 27th, 1875, and a pretty complete abstract of which is given in the November and December numbers of volume two of ENGINEERING NEWS, under the heading of "Liverpool Water Supply."

At the same meeting the Special Committee on increased supply of water was instructed to investigate the proceedings of the "contractor for tapping Croton water-mains," against whom certain allegations has been made.

HERE is an idea of what it costs to have the "beautiful snow" in large quantity in New York city:—The work of clearing away the snow and ice commenced on the 14th of January, and was kept up day and night. On the 22d less than eight miles of streets had been cleaned, at a cost of $19,982.73; the quantity removed being 38,802 loads. There are 275 miles of paved streets, of which 75 miles need to be cleaned of snow and ice. At the above rate of expenditure the 125 miles would cost $879,000, and the 75 miles $187,000: as only an unexpended balance of $9,095.20 of the appropriation remained, a requisition for more money was made on the 22d.

IN answer to a correspondent from Detroit, Mich., respecting the use of corners of permanent buildings as monuments in city surveys in Chicago, we publish the following extract, which is all that relates to the subject:

SECTION 1. *Be it enacted by the People of the State of Illinois, represented in the General Assembly:* Whenever the owner of lands shall wish to subdivide the same into two or more parts for the purpose of laying out a town, or making any addition to any city, village or town, or re-subdividing any lots or blocks therein, he shall cause the same to be surveyed and a plat thereof to be made by the county surveyor, or some other competent surveyor, which plat shall particularly describe and set forth all the streets, alleys, common or public grounds, and all the in and out lots or fractional lots and blocks within, adjoining or adjacent to the land so divided, giving the names, width, courses and extent of all such streets and alleys, and numbering all lots and blocks by progressive numbers, giving their precise length and width. Reference shall also be made upon the plat to some known and permanent monuments from which future surveys may be made, or, if no such monuments shall exist within convenient distance, the surveyor shall, at the time of making the survey, plant and fix in such manner that the same shall not be moved by frost, at the corners of some public grounds or, if there be none, then at the corners of some lots or blocks most convenient for reference, good and sufficient stones, to be furnished by the person for whom the survey is made, and designate upon the plat the point where the same may be found.

WE reprint below portions of a letter in regard to Railroad Bridge Accidents which we extract from the *Detroit Tribune*, and which is there ascribed to Mr. Geo. T. Clark, fomerly chief engineer of the Flint and Pere Marquette Railroad. We have taken the liberty of abbreviating the communication, by leaving out some parts not absolutely essential, and, while we do not agree with the writer in all points, we find in his letter some valuable suggestions:

Would it not be well before the Ashtabula horror shall have passed out of the minds of the public, for the press of the country to place the responsibility of accidents like this where they properly belong; and is it not time that some attempts be made to get at the causes producing such terrible results? In the first place, what facts has the testimony (thus far brought out) before the coroner's inquest and the Legislative committee given us in regard to the character of this structure? It appears, according to the testimony of Mr. Tomlinson, the civil engineer who was employed to make the plans and specifications of the bridge, it was what is known as the *Howe* truss, made of iron. This class of bridges made of wood has for something over thirty years been largely used in railroad construction, and have been more favorably received by American engineers than any other class of wooden bridges. And here I wish to say that Mr. Stone, the former president of the Lake Shore Railroad Company and President at the time the bridge was built, and who (according to his own testimony) designed the bridge, was the owner of the patent for constructing this class of bridges, and was for many years also a railroad bridge contractor. With him this class of bridges was a specialty. I never knew that he ever made any pretension to scientific acquirements in the art of bridge building. Mr. Tomlinson, it seems, in getting up the plans of the bridge, got into a dispute with Mr. Stone over the size of some of the braces. Mr. Tomlinson insisted that in order to give a certain required strength to the bridge they should be of one size. Mr. Stone, on the other hand, said a smaller, and, consequently, *lighter size, would answer;* and this disagreement resulted in Mr. Tomlinson's discharge from the service of the company. Mr. Stone says in his testimony, that he was inefficient. Mr. Charles Collins, however, who has for more than twenty years been chief manager of the company, sustains Mr. Tomlinson, and says in his testimony that Mr. Tomlinson was right, and that the braces should have been larger, and the whole bridge should have been built in accordance with the Tomlinson plans and calculations. Moreover, he adds in his testimony, that the bridge on the part of Stone was an experiment. After the discharge of Mr. Tomlinson, Mr. Stone employed a man to superintend its construction who never put up an iron bridge, and so

ignorant was he of bridge-building that he got many of its parts together wrong and entirely out of place. This is the testimony of Mr. Collins. With his testimony and that of Mr. Tomlinson, and we may add that of Stone himself, the responsibility of this fearful disaster must rest on Mr. Stone. He cannot get rid of it, for it was through his persistency and conceit, as chief executive officer of the company, a competent engineer was discharged and this faulty structure placed on one of the great lines of travel.

The history of this bridge leads us to say something on the subject of iron bridges.

It is not our purpose to enter into any discussion as to the relative strength of iron compared with wooden bridges, but the general use of iron is of so recent a date that it may be treated as a subject open to examination. * * * * * In many of our great railroad centers there are now large establishments devoted exclusively to the manufaturing of iron bridges, comp tition between which has now become very great. * * * * For instance, a competent engineer is called on to plan an iron bridge for a railroad, and he goes to work on it carefully, guarding all weakness in the use of material and arranging its parts in accordance with plain statical laws. When he presents his plan to the company nine times out of ten he will be told, "We cannot afford that. We must get along with something cheaper, and take the chances," The plan is shown a number of these manufacturing companies and proposals received for its construction, and the bridge let to the lowest bidder. Girders are then made lighter, bolts reduced in size and number, angle irons sheared down, and more or less poor material put into the whole structure. The engineer may protest, but it will be of no use. He will be told: "We cannot afford what you want," and as his bread depends on his employment, he has to submit. Very many of our railroads are dotted their whole length with these light fancy structures for which alone the managers of the roads are in great means responsible. Examine them closely and you will find cast-iron inserted where it ought not to be, and no allowance made for loss of strength, by heat, frost, or misplacement of load. A bridge that cannot bear up its load, if by chance the engine should leave the rail, should not be kept in place a moment. Say what you may, iron is a treacherous metal in a bridge, unless carefully manufactured and each place closely examined, tested and properly put in place.

Width of bridge is an important element of safety. A class of bridges known as flush bridges are so narrow that a person cannot stand on them with any safety while a train is passing. The track being placed on the top chord. there is nothing, in case a wheel leaves the track, to catch it, or prevent the train from turning over. This contingency is unprovided for in a great many of our iron bridges. Our engineering schools now give great attention to this part of the engineering profession, and there is no reason or justification that any thing pertaining to this construction should be left to chance or experiment.

A good bridge may become unsafe from the want of proper care, attention and frequent examination. They are usually left in the care of ignorant track hands whose early education was on the bogs of Tipperary, and their railroad experience gained in the gravel banks on the line of some American railroad. Very many of our railroad companies do not keep competent men to look after their bridges to see that the nuts and keys are tightened and loosened to meet contraction and expansion, and bridges often fail to meet the requirements made of them for want of this attention on the part of the company.

I have already extended this article to a much greater length than I first intended, but the question arises how shall we prevent the occurrence of accidents like this at Ashtabula, for it is the prevention and not the cause of accidents that we seek to reach. The question is one not easy of solution. Iron bridges must of necessity be built, and in the future more frequently than at present. Wood must give way to iron. There is no other alternative. And the responsibility in a great measure, of this dangerous construction must, and does, equally rest with the people as well as with the controlling corporations. The demanding of rapid transit involves the necessity of heavy engines, luxuriant and heavy coaches, the breaking of which is sure to deal out death and destruction. That some legislation is required on this subject no one can deny, and I would suggest, in order to give greater security to travel, that when a road desires to put up a new bridge, they shall first submit plans and specifications of the same, together with a plan and description of the abutments on which it is going to rest; also a full description of the stream or place which it is to span, to the railroad commissioners of the State, who shall take the plans and papers before described and lay them before two or more civil engineers or bridge experts, who shall examine the same in detail in all their parts and report to him, making such suggestions, alterations and improvements as they may deem necessary to secure a safe and reliable structure; and said experts shall make a certificate of same under oath, in which they shall swear that they are not directly or indirectly pecuniarily interested in the bridge, or any bridge manufacturing interest; and the railroad commissioners shall have the power to enforce the construction of the same in accordance with the report of said experts; and the commissioner shall also have the power to appoint an expert to examine all bridges now in use on all the railroad in the State and report the condition of the same to him, and if any are found unsafe the commissioner shall have the power to demand that they be put in immediate repair and in safe condition for the passage of trains; and in the event of their failing to do so within a reasonable time, he shall also have power to prohibit trains from passing over them until such repairs shall have been completed. Something like this, in my opinion, would, in the event of an accident, tend to relieve the company of much of the responsibility that would otherwise rest on them, and add much to the safety of the traveling public.

I would add that in the preparation of this article I am indebted for some of the suggestions in regard to iron bridges to an article on the same subject published in the Boston *Evening Transcript* a few days since.

G. T. C.

THE ASHTABULA CALAMITY.

SKILL AND CONSCIENCE IN BRIDGE BUILDING.

To the Editors of the Boston Daily Advertiser:—

Before the interest in the subject of bridge construction, which the above-named disaster has called forth in the public mind, has entirely abated, and again none but we sentinels whose business it is to be constantly on guard are left to study the lessons it and other failures, as well as bright examples of success, have taught us; before the recollection in this and other bridge failures has again grown so dim that an engineer's words of warning, his desire to build only the best, and his feelings of responsibility, which few but he can rightly estimate, are all again lightly valued, I wish to say a few words upon this last and sorrowful bridge failure, to the general public. I feel called upon to do so in answer to questions and representations such as these:—

What was the cause? Was it improperly constructed? Was the iron of inferior quality? After eleven years of service, had it 'suddenly' lost its strength, or had a 'gradual' weakness grown upon it unperceived? Might that weakness have been discovered by frequent and proper examination, or was the breakage the sudden effect of intense cold? If so, why had it not happened before in yet more severe weather? Is there *no* method of making iron bridges of assured safety? And who is responsible, so far as responsibility goes, for such an accident,—the engineer who designed the bridge, or the contractor, or the builders, or the railroad corporation? Was the bridge, when made, the *best* of its kind, or the *cheapest* of its kind? Was the contract for building "let to the lowest bidder," or given to the most honest, thorough workmen? These and a hundred similar queries arise in every thoughtful mind, and an anxious community desire information and assurance of safety. The majority of people cannot, of course, understand the detailed construction of bridges, but they do desire confidence in engineers, contractors, manufacturers, who have to do with the making of them, and in the railroad companies, into whose hands they are constantly putting their own lives, and the lives of those dearest to them. —*Harper's Weekly*, Jan. 20.

The sources of my information are: In a general way, a seven years's study, followed by thirteen years practice as a constructing engineer; with particular reference to the Ashtabula bridge failure, a collection of all the principal railroad and weekly engineering journals published in this country since the breaking down of the bridge, editorials and communications in most or all of the New York and Boston papers to date, and the report made by a skillful bridge-builder, after personal inspection, to a society of civil engineers.

"Was it improperly constructed?" This question can be analyzed into several others: Was the design or outline a faulty one? Was the material a proper one, and enough of it in the proper places? Were the several parts properly joined together? Was the work of construction and of erection properly executed?

The general design or outline of the bridge was that of what is called a "Howe truss"; the track over the trusses; inclined, not vertical, end posts. The Howe truss is so-called after William Howe of Warren, Mass., who first built these trusses of wood, with iron vertical tension-rods, and is the wooden truss oftenest met with. It will be recognized by all from its general characteristics: wooden diagonals and top and bottom chords, iron vertical tension-rods. And such a general system of lines or members is a good one.

Something has been said about an arch having been added to the truss, to "strengthen it," when the bridge was first built or some time afterwards. This does not seem to be correct, yet, as it formerly was often done and is still often urged, I take the occasion to say that such a general design is a bad one. A proper truss needs no "strengthening." If it could not be made just as strong as wanted, by itself, it would not be a proper design. It *is* capable of being made of any desired strength. By so doing, the exact amount of load that each member bears at any moment is mathematically fixed, a determination that is lost as soon as either an arch or a suspension cable is added to the truss; hence there is no valid reason why the truss design alone should not be constructed to do its work, whenever the structure pretends to be a truss or beam bridge.

Was the material a proper one, and was there enough of it in the proper places? The evidence shows the material of all the principal parts to have been wrought iron, a proper one in general, and I think of good quality in this instance; and, although it is in evidence that the designer and engineer of the bridge was not allowed to have his way as to the quantity of material in the end braces, but was overruled, and on account of such disagreement between them was discharged by the President of the board—yet, notwithstanding this (upon which point some may lay undue weight), I gather from all the testimony, that the amount of material in all the members of the bridge was such that the bridge did not give way by reason of the failure of any of them from being overloaded. I answer, therefore, that the material of the main parts of the bridge (the joints I consider later) was *not* of "inferior quality," did not "*suddenly* lose its strength," had not "a *gradual* weakness grow upon it unperceived," there was nothing in this direction to discover by "frequent and proper examination."

Were the several parts properly joined together? We touch here upon a most delicate question for a single engineer to answer categorically; for it is precisely upon this question that a discussion has been going on among engineers and bridge builders in this country for the past two or three years, and the subject is one of individual opinion still. It behooves every one, however, to clearly state his opinion, especially so at the present time, to state it calmly, dispassionately and unbiassed by personal interests.

The Ashtabula iron bridge was constructed with a system of joints which latterly has been claimed with pride as peculiarly "American;" without proper reason, perhaps, for it did not originate here, nor is it the only kind in use in the United States. For example, none of that kind are on the New York Central or Hudson River Railroad, nor on our Boston and Albany road; the Connecticut river bridge near Windsor Locks is not of that kind, nor is the Allegheny river bridge in Pittsburg; several American bridge contractors build none of that kind; many American engineers have never, and do not now, design such bridges. But however all that may be, engineering literature has been full of articles on the respective merits of "American" and of "European" or "riveted," iron bridges. There are, of course, several qualities of the "American" or hinged, or butted (as I shall prefer to call them) styles of joint, and Ashtabula was not one of the best; still it is a general characteristic of them all, that *parts in compression are merely butted one against the other, or cast iron is used in short sleeves or "joint boxes"* to help make the joint, whereas a fundamental rule in "riveted" structures is to joint or attach members in compression by rivets, placed and headed while red hot, just the same as members in tension.

There is another characteristic of the falsely so-called "American" style of bridge, in having for tension members single and separate forgings of iron, ending in round eyes, these eyes strung on a single large pin, whereas, in the 'riveted" structure, these same tension members are composed of many smaller pieces, riveted together, and all of these are attached by riveting, as already stated. And still another characteristic difference may be pointed out in the frequent use of bolts and nuts in the first, where the other again uses only rivets, placed and headed up while at a red heat. The discussion spoken of above has taken a wide range and has included considerations of first cost of economy in erecting the bridge, and many more; but as we are now considering solely the question of safety, I, for one, think clearly that in all three of the characteristics above pointed out, and more especially for railroad purposes, the riveted structure is the safest. A heated partisan of the other opinion has gone so far as to argue that because in case a hinged or butted-joint bridge falls into the river, on account of the stone piers being undermined, it falls all to pieces, and the pieces can all be picked up and put together again, and because a riveted structure under like circumstances holds together so well that it requires, and in an actual case did require, dynamite and a good deal of work to reduce it to old iron, and get it out of the way, that therefore the first described structure was the better one. And it certainly is, under those particular circumstances.

But bridges are not built to tumble into rivers and come out unharmed in their several parts; their object in this world, as I understand it, is a different one. It is to afford safe transit over themselves as long as the stone piers stand erect, and the object of the stone piers is to stand erect for the immediate support of bridges. And now reverse the proposition; instead of having the bridge strike in its fall against the river bottom, let the bridge stand still, and have, not exactly the bottom of the river, but any other ponderous body, a derailed locomotive or car-truck, etc., strike it. In such event—not an uncommon one—is it not clear that the bridge that fell all to pieces easiest before will do so again? I think the subject needs no further illustration. Here are the advocates of the one system of making the joints of bridges by their very advocacy condemning their structures for the purpose of withstanding sudden and unexpected shocks, unexpected alike in direction as well as amount. I have, in my own experience, seen a riveted truss while it was being erected, and before it was connected with any other part of the whole bridge, get blown off the abutments by a gust of wind, and fall eighteen feet to the track below; it was lifted up, a fire

built under the corner where it struck first, so that *that* could be straightened out; it was put in place, and is there to-day, after twelve years of service, and this was a cheap kind of a concern at that. Perhaps this behavior is better yet than falling all to pieces, but, in my opinion, the value of the accident was to give a rude measure of what such trusses would endure when in place, and not as they fall.

Something ought to be said here about the use of cast iron in bridges. Many engineers, who will not use it for principal members, still excuse its use in "joint boxes" of butt joint bridges. Riveted bridges use none in any shape. As practice is better than all theory, I begin with the recital of such iron bridge failures as I remember, and add the cause of their failure as I understand it:

Over the Dee, at Chester, England, 1847. Cause, union of cast and wrought iron; bad design.

On the Erie Railroad, 1850. Cause, insufficient material; union of cast and wrought iron.

Over Joiner street, London, October, 1850. Cause, bad design; union of cast and wrought iron.

Czernowitz bridge, Austria, 1868 or 1869. Cause, bad system of joints; union of cast and wrought iron.

Bridge at Dixon, Illinois, May 4th, 1873. Cause, insufficient amount of material and not a first-class kind of design.

This was a road bridge; all the rest and the following one were railroad bridges:

Ashtabula, Ohio, December 29, 1876. Cause, bad system of joints, involving the use of cast iron, and improper work in building and erecting.

The value of this table depends almost entirely on the fact that during an extensive course of reading, this table contains *all* the cases of iron bridges breaking down under their load, that I have met with. Here is a record of thirty years, and cast iron plays a prominent part in all but one of the six cases; and there is no record, as far as I am aware of, of a wrought iron riveted bridge ever having broken down, though some are standing that were built in 1845 and 1846, and although they, as well as all other kinds, had to pass through stages of incomplete development to their present relative state of perfection.

The theoretical reasons for the breakage of cast iron in bridges are several: When introduced as a principal member, with wrought iron, it is shortened by compression in a different ratio from wrought iron, it is expanded and contracted by heat and cold in a different ratio than is wrought iron, both undesirable attributes, to say the least. When used in short pieces or in long ones, it is liable to break by a sudden blow; this liability is largely increased in cold weather; it is a treacherous material at best, breaking, when it does break, without warning. Experiments *have* been made many times to show that cold has no effect on the strength of wrought or cast iron, but they are not conclusive; they only show, one and all, that in the laboratory, under a quiet pull, the application of a freezing mixture produces no change.

The practical fact still remains, to cite no others, that cast steel stone-hammers, when left out over night, are apt to break with the first blow struck in the morning, while if previously warmed up they do not do so. Nor is it entirely outside the bounds of reason to devise and test a theory to meet such cases. Think, for example of the part that the heat produced by a blow is likely to play in these breakages. The rap of a piece of steel on a flint is no tremendous power, and yet it causes enough heat to ignite the particle of steel chipped off, and thus makes the spark that sets fire to the tinder. Can it not be that the intense heat produced in the one point of contact by a blow may have something to do with it, if it is not the *sole* cause of the sudden shivering of a mass of matter permeated by frozen moisture, or more contracted on the outside than it is in the body of it? Then, again, we have the fact that cast iron in cooling often locks up within itself very great internal strains; a homely example of this tendency of all castings are the "Prince Rupert's drops" of glass, that fly to pieces of their own accord as soon as a small piece is broken off them. What a slight breakage does to the one, another trivial cause may produce in the other. I answer, therefore, that the "sudden effect of intense cold" *may* have had something to do with the breakage of that kind of a bridge, and while I will not with one sweep and in one common lot condemn all of the so-called "American" style of bridges, including, as they do, many qualities of bridges, some the work of some of our ablest engineers, men whom all of us respect and honor, I yet must say that simple butt-joints and cast-iron "joint-boxes" should go where are going cast-iron principal members, *out of use;* a large field lies still open to the builders of these bridges in improving and perfecting them, and to the question, "Is there *no* method of making iron bridges of assured safety?" I answer that a wrought iron riveted bridge is, under a test of thirty years experience, beginning at their infancy and extending to the present time, when designed by a competent person, and their construction superintended by such an one, "an iron bridge of assured safety."

Was the work of construction and of erection properly executed? The testimony in the present instance would be a most curious picture of the way not to build a good bridge, were not one or more of its salient features so very common, sad to say. The bridge was designed by an engineer, who is vouched for to me by a competent judge as "honest and conscientous, a firm believer in good material and plenty of it." The President of the road disagreed with this engineer on the manner of constructing certain principal members of the bridge, and, as he says, "Mr. ——— was discharged for inefficiency."

To comment on this is, perhaps, unnecessary; but the kind of "inefficiency" here alluded to is evidently of the kind sometimes given as "sufficient grounds for a divorce," under the name of "incompatibility," a conscientious engineer being *unable*, without the possession of much tact, to remain in the service of some railroad Presidents or Superintendents. Upon this says the President, "Mr. R. was put in his place; Mr. R. had no experience either before or since in the erection of iron bridges, so far as I know." And before the *erection* of the bridge,—'The iron-work was done by as thorough a master-machinist as I know of.' And what says this master-machinist for himself; "I never calculated the strength of tension or compression members; did not say much to any man about the bridge, as I did not consider myself a competent bridge man." Under all these circumstances it almost follows, as a matter of course, that, as testified to, mistakes were made in constructing the bridge—in erecting it parts were at first put in the wrong places; the camber (rise above a perfectly horizontal line) was at first the wrong way, a rise *down* instead of up; this had to be patched up—and, finally, that we shall probably never know what, if any, hidden mistakes or defects the structure may have contained. In any event it does not seem to have had the immediate, daily supervision, care, nursing and improving which every constructing engineer knows to be of the greatest value, that a structure gets when executed by competent brains and hands. Under the circumstances it seems clear that this bridge was therefore *not* "the *best* of its kind," although still far from being "the *cheapest* of its kind," and that the mode of construction and erection left much to be desired.

I come to the moral of the lesson as I understand it. If the responsibility for failures of this sort is to appear clearly and without doubt, some individual class of men must be entrusted with the construction of bridges. There are in every community educated, experienced constructing engineers whose *business* it is to bear such a responsibility; they are *fitted* for it, competent to insure "with their head, if you ask it," as George Stevenson said, the safety of the structures they erect. All *they* ask is that their advice be taken, not overridden by the fancy, perhaps, of a moment. As now too often situated these men are not allowed to build as they know it is proper to build, and yet when anything occurs, the eye of every one is at once turned to them, and them only. A melancholy interest attaches to this part of the subject by the suicide of the chief engineer of the road on which the Ashtabula-bridge failure happened. With the experience of the designer of that bridge before him, an obstinate standing out for his own views would hardly have effected his objects, and tact will not do everything. I desire again to refer to my own practice, and make the statement, that as I look back to the various structures nominally mine, in various places, the rule is that they are the children of ingenious compromises, not such as I would proudly call my own.

If the public will distinguish between surveyors, railroad stakers-out, master-mechanics, professors of mathematics, contractors and constructing engineers (civil engineers I would say, but that the term has well-nigh lost its meaning; if they will appreciate that where the one party to a bargain is (they will pardon the expression) either ignorant of, or what may be equally bad, only a little educated upon a subject, and the other party is knowing and is in the competition with a score of others equally sharp, all trying to beat each other in a race; if they will appreciate that under these circumstances it is the order of nature and of human nature that there is legitimate work for those who have devoted themselves to the full knowledge of the subject matter, without pecuniary interests in who wins the race, and only striving to serve the first party named, then the service of constructing engineers will find its true appreciation.

There is only one correct way of building bridges or large roofs; a constructing engineer must design the bridge or roof; his plans can be changed in details until satisfactory to the parties that pay for it, and all contractors must bid on that one plan. This is fair to all. This is the way all the bridges on the Pennsylvania railroad are built, it is the way they are built on the Boston and Albany road, it is the way bridges are built in Europe universally—it is the only *safe* way. It places the responsibility where it belongs. The distinction between competent civil engineers and gentlemen *not* civil engineers, between engineers and contractors, must be sharply drawn. It will undoubtedly surprise many engineers who have left the profession and taken up bridge contracting, to be told that they *are* no longer of their former profession, and have changed their very nature. But human nature is such and cannot be changed. "No man can serve two masters," and when it comes to advising upon bridge construction, or selecting between several bridge plans, the contractor or "bridge builder" is incompetent by reason of personal interest. We must take a leaf here from the experience and practice of the gentlemen of the law, who for ages have kept the attainment of exact justice and impartiality in view. It is with a feeling of mortification, no doubt, and perhaps with a heavy heart, that a justice of the Supreme Judicial Court sometimes steps from the bench and declines to hear a case in which, say, a railroad company is a party, because he or his wife may own a couple of shares in the road; yet the foundations of justice rest upon such acts; and it is equally proper that the contractor should be equally cautious in giving his opinion free from the taint of any personal interest, and should be encouraged by the public when he is so conscientious as to dislike acting as engineer and contractor both. I believe that all conscientious contractors, men who desire to advance the quality of bridge-work and stamp out the whole tribe of poor workmen and poor work, are anxious to *have* the public have confidence in competent constructing engineers. There is no conflict between the two, for they work in harmony toward the attainment of the same ends.

With that part of the public whose duty it becomes to employ civil engineers, these engineers and the contractors, or the master-mechanic, working together in harmony, and each in his proper sphere, such failures—I decline to call it an accident—as that at Ashtabula will become exceedingly rare, and, should one ever occur, the responsibility ought to, and will, come home like lightning to the proper party.

I remain yours, etc.,
CLEMENS HERSCHEL,
Boston, Jan. 23d, 1877. Civil Engineer

CORRESPONDENCE.

BOSTON, *Jan. 25th, 1877.*

EDITOR ENGINEERING NEWS:

SIR.—In perusing the address "Rise and Progress of American Engineering," reported in your journal of 13th inst., I find several inaccuracies which should not be allowed to pass unnoticed.

First, it is asserted, that a canal connects Washington with Pittsburgh.

Second, that the "National Road," beginning at Washington, passing through Wheeling, terminates at St. Louis.

Third, that a "branch" road (independent) connects Baltimore with Wheeling; and, Fourth, that by means of said roads, time of transit was reduced from eight to three days.

Now the facts are these: The original plan was to connect the Chesapeake Bay with Ohio River, by means of a canal to be known as the "Chesapeake and Ohio," and, no doubt, would have reached its destination, as the object was to bring the coal fields of western Alleghany in *direct* communication with the seaboard, had not the principals in the stupendous undertaking been agreeably disappointed in the full prosecution of the plan, by the discovery of a *better* article of coal in the *eastern* Alleghany, near Cumberland, Md., which latter place *is* the present terminus of the "Chesapeake and Ohio canal," and *not* Pittsburgh.

As to the second statement, almost every school boy in Western Maryland knows that there is but *one* "Turnpike," "National," State or individual, running to Wheeling from Washington and Baltimore, the "branch" which is stated "was constructed to Wheeling" from Baltimore, has no existence farther west than Frederick City, Md. (48 miles from Baltimore), where it unites with the "National Road" and from there is known *only* by the latter name, and only by *that* name as far as Wheeling where it ends as a "*National Turnpike.*"

The fourth, and last declaration to which objection is taken, reveals an error of judgment as well as of fact. We are asked to believe "the time of transit was reduced," by the improvements referred to "from eight to three days." A glance over any accurate map of the United States will show that Wheeling is 250 miles on an *air line*, from Washington, and Baltimore, and about 300 miles by the "National Road." Now, all "old wagoners" agree, that with the advantages referred to, "two-and-a-half miles per hour was pretty fair travelling" when "loaded," and that fifteen hours was an average day's work; by which it would appear that eight days was necessary, even with *good* roads, to the performance of the journey. Indeed, when the enormous size of the wagons used is taken into consideration, laden as they were with from five to eight tons burthen, and drawn over mountains whose summits pierce the clouds, by hard-worked and jaded horses, the wonder is that so great and difficult a task could have been accomplished even in ten or twelve days, and wholly dissipates the assertion that it ever was done "in three days."

Those who stand in such relation to the people that their utterances are taken as matters of fact, should take more pains to inform themselves *thoroughly* about whatever subject they may have to deal with, and not impose on a confiding public.

Let us have things right. MARYLANDER.

TORONTO, *Jan. 26th, 1877.*

EDITOR ENGINEERING NEWS:

SIR.—In the construction of railways, or in renewing the station buildings of old lines, placing the station buildings—especially those for passengers and freight—on that side of the line from which the greater amount of traffic must come, will in so-far reduce the danger to vehicles or pedestrians from passing trains. Experience shows that by far the greatest number of accidents occur at those stations where the buildings stand on that side of the line farthest removed from the hamlets, villages, or towns or whose outskirts such stations are generally located. The reason for this is too obvious to require explanation. Indeed, legislation should secure to the public the proper location of station buildings on all new lines, and the alteration of those on existing lines whose positions are inaccessible save at the imminent peril of property, limb or life.

The Hamilton and Northwestern R. R. bridge over the Burlington canal, near Hamilton was formally opened with some ceremony on the 10th inst. It is an iron swing trapezoidal truss. Depth of truss in the middle, 31 feet, at each end, 24 feet; length 372 feet

Work on the section of the Montreal, Ottawa and Occidental R. R., between Hull and Aylmer, is being pushed rapidly forward this winter. It is to be ready for the passage of trains in July next.

Mr. V. B. Wadsworth, leading partner of the late firm of Wadsworth, Unwin and Browne, Provincial Land Surveyors, of this city, having been appointed Inspector to the London and Canadian Loan and Agency Co. Messrs. Unwin and Browne continue business in the same office on Adelaide street and will, doubtless, well sustain the reputation of the late firm.

The process of *straining* the recent budget speech of the Hon. Adam Crook, in the Ottawa Assembly, yields the following, of interest to railway people and others:—Notwithstanding the liberal grants of aid to various railways within the past year, on the 31st ult, this province rejoiced in the possession of a surplus of something over $4,873,000. Following out the policy inaugurated by the late Mr. Sandfield Macdonald's government—that of granting aid, to a limited extent, in the construction of railways into districts needing them—about $33,000,000 have been advanced for that purpose out of the Provincial funds between the years 1867 and 1876. And this policy has led to the expenditure in the aggregate of $33,000,000 in railway construction

within the same time—not taking into account the Great Western Air Line, the Canada Southern R. R., and portions of the Toronto, Grey and Bruce, and of the Toronto & Nipissing R. R., which did not receive aid from Government. After allowing for the $3,000,000 contributed by Government the great bulk of the remaining $30,000,000 has been raised from local sources, various municipalities interested having contributed over $7,000,000 in bonuses. In 1867 to 1873, inclusive, 1018 miles of railway were built; i 1874, 92 miles; in 1875, 186 miles, and in 1876, 165; total, 1867 to 1876, inclusive, 1461 miles, completed. The wisdom of the Province's railway policy has been clearly demonstrated in the sound, even though depressed, condition of the Province to-day.

From the report of the Victoria Railway Co., just published, it appears that negotiations are nearly completed for the purchase of engines and rolling stock sufficient for the traffic of 1877. The Company have applied to Parliament for a subsidy of $12,000 per mile in aid of the completion of the railway through to the mouth of the Mattawan river, on the upper Ottawa. The Canadian Land and Emigration Co. has agreed to give to the railway company a bonus of $3,000 per mile through that Company's territory.

In your issue of the 13th inst., under the head of "Railroad News," you say: "They are still 'signing contracts' to build Sec. 15 of the Canada Pacific R. R. It is about as far as the section will ever get, or ought to get." Now, all parties interested deeply regret the delays in the letting of the contract above referred to. But these little "hitches," and *rings*, and things, are not peculiar to Canadian soil. It is said they have been heard of even south of the great lakes. And, feeling as we do, implicit confidence in our ability to perform whatever, after mature deliberation, we undertake, we Canadians shall feel obliged if you will "rise and explain" what you mean by the latter sentence above quoted. Is it that the Canadians should have better taste than to construct a formidable rival to the Northern Pacific R. R.? CANADENSIS.

The money now being wasted on this wilderness road to nowhere, might much better be expended in improving existing roads.—[ED.

BOSTON, *January, 1877.*

Editor ENGINEERING NEWS:

SIR:—The following method of keeping level notes I have used with success, especially on long lines of levels, in my practice as engineer of the Fitchburg R. R.

The elevation of each station is found by adding, algebraically, the difference between each reading of the rod, in succession, to the last elevation.

For example, the difference between the readings of the rod at Stas. 0 and 1 is added to the elevation of Sta. 0, giving the elevation of Sta. 1. In the same way the elevation of Sta. 2 is found by adding the difference in the reading of Sta. 1 and 2 to the elevation of Sta. 1.

It possesses the advantage that the elevation of any Sta. can be *checked* at once by adding the sum of any number of differences to their first elevation. This will be readily understood by reference to the following example, taken from my note book:

Sta.	B. S.	F. S.	Diff.	Elv.	Remarks.
0	7.408			284.364	
1		6.57	+0.838	285.202	
2		5.70	+0.87	286.072	
3		5.64	+0.06	286.132	
4		5.50	+0.10	286.232	
5		5.52	−0.02	286.212	
T. P.		5.217	+0.303	286.515	
	6.671				
6		6.13	+0.541	287.056	
7		5.28	+0.85	287.906	
8		5.24	+0.04	287.946	
9		3.93	+1.31	289.256	
10		3.93	+0.00	289.256	
11		4.20	−0.27	289.986	
12		3.28	+0.92	289.906	

To check the elevation of Sta. 12, add (algebraically) the differences from the last station checked, say No. 5, to the elevation of No. 5; thus:

Elevation of No. 5 = 286.212 + (.303 + .541 + .850 + .040 + 1.310 − .270 + .920) = 289.906 = elevation of Sta. 12.

A separate column is used for + and − sights if the ground is very irregular.

For accurate work, on long lines, this possesses a great advantage over the ordinary method.

Never having seen it in print, I venture to hope that it may be new to some of the readers of ENGINEERING NEWS

J. FRANCIS LEBARON.

PLAQUEMINE, LA., *Jan. 17th, 1877.*

Editor ENGINEERING NEWS:

SIR:—There has been an unusual number of "caves," or "land-slides" on the lower Mississippi this winter, and this reminds me of a question, perhaps a scientific one, which I would like to propound: Why is it, that these "land-slides" occur *almost* always at night? To put the word "almost" in figures, I should say 99 in a 100, and feel safe that I am within bounds.

These cavings will subject our poor, politically-stricken State to a terrible devastation from the spring flood. And as we are too exhausted, too flat down with taxes and other robberies, we have nowhere to look to for help but to the national legislature. This institution is, however, too much engrossed with the problem "How to elect a defeated candidate," to give us any attention. Couldn't the question of "Mississippi Levees" be brought before Civil Engineers' Societies in some shape?

E. G.

PORTLAND, ME., *Jan. 24th, 1877.*

Editor ENGINEERING NEWS:

SIR:—Your Paw Paw correspondent informs us that he and his friends of respectability, do not use *Gurley's cheap instruments*, but use Young's (cheap instruments). A left-handed compliment to Young, and an intended fling at Gurley. Such flings are unjust to most any manufacturer. Your own reference to Gurley might be distorted into one, but I had not understood it as such, and do not think you so intended. The word "cheap," as used in your Special for Surveyors, refers, as Paw Paw acknowledges, to the cheap drawing instruments, etc., etc., of unknown manufacturers, that you can buy in most hardware or stationers' stores.

Strictly speaking, the best manufacturers do, according to my experience, and should, as I believe, manufacture cheap instruments. Many conceit themselves to certain purchasers that they do not, but they are easily confronted with the evidence of the fact. How many of us have groaned when we have caught an ambitious assistant, or fresh diplomad C. E. probing or handspiking the very life out of our "made to order instrument." It is for such noviciates that the cheap and passably accurate, but short-lived instruments, should be made. Accuracy, combined with long-living material, determines the rank and value of instruments. The young engineer but rarely enters immediately upon work of great importance; in fact, he becomes quite anxious and even gratified at a chance to air his transit upon a simple house lot or quarter section, and he marks the first few *engineering jobs* with "white stones." During this period it is foolish to hazard the expensive first-class instrument, but the passably accurate, but short lived, and necessarily cheap one, is just commensurate with the period.

My loyalty to Gurley was occasioned by a little incident while I was on the tunnel division of the Central Pacific R. R. Having heard the envious and jealous talk of small manufacturers, I was quite affronted at having an old "Gurley" thrust upon me. Submitting, I overhauled it and probed it gently, and it proved to be the peer of any instrument of that variety that I ever used. It occasioned me to purchase the one that I now have, and pay, not for a *cheap*, but for a good one, and for the price, it equals, if it does not excel, that of any other manufacturer.

JUSTICE.

SURVEY OF THE PUBLIC LANDS—HOW TO TELL TOWNSHIP AND SECTION CORNERS.*

(*Continued from page 26.*)

The parallelograms formed by the base line, principal meridian, standard parallels, and guide meridians, twenty-four by forty-eight miles in extent *north* of the base line and thirty by forty-eight miles *south* of the base, constitute the frame-work of the rectangular system of surveys. These parallelograms are each subdivided into townships six miles square, containing, as near as may be, 23,040 acres, and again each township is subdivided into thirty-six sections one mile square, containing as near as practicable, 640 acres each. The sections of one mile square are the smallest tracts the outboundaries of which the law requires to be actually surveyed. Their minor subdivisions are defined by law, and the surveyors-general, in protracting township plats from the field-notes of sections, designate them in red ink, the lines being imaginary, connecting opposite quarter-section corners, thereby dividing the section into four quarter-sections of 160 acres, and these, in their turn, into quarter-quarter sections of 40 acres each, by imaginary lines starting from points equidistant between the section and quarter-section corners and running to opposite corresponding points. The lines of public surveys over level ground are measured with a four-pole chain sixty-six feet in length, but with a two-pole chain where the surface is broken and hilly. Where uniformity in the variation of the needle is not found the public surveys are required to be made with Burt's improved solar compass, or other instrument of equal utility, operating independently of the magnetic needle; but where the needle can be relied on the ordinary compass may be used in subdividing and meandering.

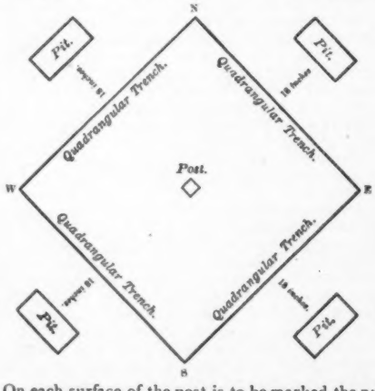
HOW TO TELL CORNERS.

The following extracts from the Manual of Surveying Instructions illustrate the manner of establishing the corners of the public surveys:

Township, sectional, or mile corners, and quarter sectional or half mile corners, will be perpetuated by planting a post at the place of the corner, to be formed of the most durable wood of the forest at hand.

The posts must be set in the earth by digging a hole to admit them *two feet* deep, and must be very securely rammed in with earth, and also with stone, if any be found at hand. The portion of the post which protrudes above the earth must be *squared* off sufficiently smooth to admit of receiving the marks thereon, to be made with appropriate marking irons, indicating what it stands for. Thus the sides of *township corner posts* should square at least *four* inches, (the post itself being *five* inches in diameter), and must protrude *two feet* at least above the ground; the sides of *section corner posts* must square at least *three inches*, (the post itself being *four* inches in diameter, and protrude *two feet* from the ground; and the *quarter section corner posts* and *meander corner posts* must be *three* inches *wide*, presenting *flattened* surfaces, and protruding *two* feet from the ground.

Where a township post is a corner common to *four* townships, it is to be set in the earth *diagonally*, thus:



On each surface of the post is to be marked the number of the particular township and its range, which it *faces*. Thus, if the post be a common boundary to four townships, say *one* and *two*, south of the base line, of range *one*, west of the meridian; also, to townships *one* and *two* south of the base line, of range *two*, west of the meridian, it is to be marked thus:

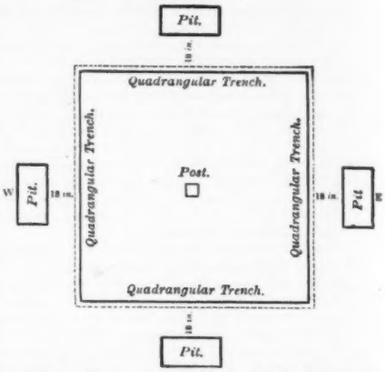
From N. to E.	R. 1 W. T. 1 S. S. 31	From E. to S.	1 W. 2 S. 6
Fram N. to W.	2 W. 1 S. 36	from W. to S.	2 W. 2 S. 1

* From Copp's Land Owner.

These marks are not only to be distinctly but *neatly* cut into the wood, at least the eighth of an inch deep; and to make them yet more conspicuous to the eye of the anxious explorer, the deputy must apply to all of them a *streak* of *red chalk*.

Section or mile-posts, being corners of sections, and where such are common to *four* sections, are to be set *diagonally* in the earth, (in the manner provided for township corner posts); and on each side of the squared surfaces (made smooth, as aforesaid, to receive the marks) is to be marked the appropriate *number* of the particular one of the *four sections*, respectively, which such side *faces;* also, on one side thereof are to be *marked* the numbers of its *township* and *range;* and to make such marks yet more *conspicuous*, in manner aforesaid, a streak of *red chalk* is to be applied.

The following represents a corner mound common to two townships or two sections only:



In every township, subdivided into thirty-six sections, there are twenty-five interior section corners, each of which will be *common* to *four* sections.

A quarter section or half-mile post, is to have no other mark on it than ¼ S., to indicate what it stands for.

NOTCHING CORNER POSTS.

Township corner posts, common to four townships, are to be notched with *six* notches on each of the four angles of the squared part set to the cardinal points.

All mile posts *on township lines* must have as many notches on them, on two opposite *angles* thereof, as they are miles distant from the township corners, respectively. Each of the posts at the corners of sections in the *interior* of a township must indicate, by a number of notches on each of its four corners directed to the cardinal points, the corresponding number of miles that it stands from the *outlines* of the township. The four sides of the post will indicate the number of the section they respectively *face*. Should a tree be found at the place of any corner it will be marked and notched as aforesaid, and answer for the corner in lieu of a post, the kind of tree and its diameter being given in the field-notes.

The position of all corner posts, or corner trees, of whatever description, that may be established, is to be evidenced in the following manner, viz.: From such post or tree the courses must be taken and the distances measured to two or more adjacent trees in opposite directions, as nearly as may be, and these are called 'bearing trees." Such are to be distinguished by a large *smooth blaze*, with a *notch* at its lower end, facing the corner and in the blaze is to be marked the number of the *range*, *township* and *section;* but at quarter section corners nothing but ¼ S. need be marked. The letters B. T. (bearing tree) are also to be marked upon a smaller blaze directly under the large one, and as near the ground as practicable.

At all township corners, and at all section corners, on range or township lines, *four* bearing trees are to be marked in this manner, one in each of the adjoining sections.

At interior section corners, *four* trees, one to stand within each of the four sections to which such corner is common, are to be marked in manner aforesaid, if such be found.

A tree supplying the place of a corner post is to be marked in the manner directed for posts, but if such tree should be a beech, or other *smooth bark* tree, the marks may be made on the *bark*, and the tree notched.

(*To be continued.*)

THE PROPOSED DETROIT TUNNEL.

There have been two or three meetings of citizens of Detroit and others interested in the project; yet little definite progress seems to have been made. Several plans have been submitted and others have been talked of. Gen. Wm. Sooy Smith came prominently forward and stated that he had obtained pledges from gentlemen of means to advance the money necessary to build his tunnel, provided they were guaranteed the interest on the money thus invested. While he could not approximate to the probable cost before a survey was made, he did not believe that it would be greater than for a double track iron bridge and, to decide the matter, he would be willing to make the necessary surveys himself. Mr. P. H. McWilliams proposed to construct a tunnel from a crib sunk in mid-stream, and to have a rising grade archway from the middle, so that the tunnel should drain towards the crib, and the water be pumped out by power at that point. Unfortunately for the respectability of this scheme, the inventor proposes to make a place of resort of this central crib or caisson, on payment of a fee, turning it into an island by means of the refuse excavated material, and opening the shaft and tunnel to visitors by means of an elevator worked by the pumping engine, while he would crown the whole by a lighthouse for the benefit of navigators.

Mr. Eugene Robinson has invented what he calls a portable coffer-dam for tunneling. The dam consists of a float made of boiler iron and timbers, 40 x 80 feet in extent, and five feet deep, forming a chamber which, filled with water, enables the operators to sink the machine. From the centre of this float rise two iron shafts of sufficient height to project well above the surface of the river. On the bottom of the float is a sharp steel shoe which, being pressed into the earth, excludes the water. When anchored at the bottom the water is pumped out of the large chamber, and workmen go down the shafts, at the bottom of which they can work in security. This device will therefore be seen to be analogous to the caissons which have been used at St. Louis and Brooklyn, but is evidently intended to be moved from place to place. We apprehend that the nature of the bottom would have a decided influence upon their successful operation, and no provision seems to be made to weight the coffer or caisson sufficiently to get penetration, and then to admit of removal. However, it is reported that he and his business partner, J. H. Farwell have confidence in their ability to construct a tunnel with its aid, and offer to build one 20 feet in diameter, for $3.500,000, depositing $50,000 in advance. to be forfeited in case of failure, and agreeing to take $500,000 in Tunnel Company stock.

A device of cast or wrought iron sections of cylinder, sunk in line, and joined by flanges and bolts, meets with favor from some. The plan of the tunnel projected a few years ago, whose construction was entered upon and then abandoned, is still considered feasible by many, among whom may be mentioned Mr. Chesbrough, the engineer who proposed it. It was to consist of two parallel tunnels seventy feet apart, one for each track, with a small drainage tunnel below. The tunnels were to be about two miles long, and ninety feet below the water level, the river being about fifty feet deep. This small tunnel was commenced, and after advancing several hundred feet, at an expenditure of some $100,000, and meeting with two or three influxes of sand and water, was stopped. The engineer has stated that he did not desire to increase his estimate of cost, and that he still believed it practicable, We never could see any good reason for abandoning the work, aside from the hard times of 1873-4. unless it was that the railroad officials were pre-disposed in favor of a bridge and thought that permission for one could be obtained from Congress and the Canadian government.

Mr. James F. Joy has, until recently, been the controlling power of the Michigan Central Railroad, and his co-operation was, of course, necessary. What he thought of General Smith's proposal is readily seen in the following letter:

DETROIT, January 22d, 1877.

MY DEAR SIR—I have yours relative to Tunnel Committee and my appointment upon it, for which please accept my thanks.

It will not be possible for me, however, to attend this week, as I am going to New York this evening.

It is, however, of not much importance, because, in my judgment, no such tunnel as Mr. Smith proposes is practicable. Where water is fifty feet deep, and moving from two and a half to three miles an hour, and with twenty feet of soft mud in the bed of the river under it, a part of the way, and hard clay for a part, it is clear that the top of the tunnel must be some more than seventy feet below the bed of the river. This will make it necessary to excavate the bed of the river, all the way across, to the depth of about ninety feet below the surface to the bottom of the tunnel, and in the clay and mud, a depth of from forty to sixty and eighty feet deep, depending upon the depth of the water. This excavation *in the bottom* of such a river across it, *if practicable at all*, will be attended with such expense and difficulty as to be nearly, if not certainly, impracticable, *and so expensive as to be wholly impossible, with any means which can be commanded.*

My presence therefore cannot be very important, though I am obliged to you, and were it possible should be glad to help along. As it is, it is one of those visionary schemes which will serve to divide us, and delay all action till a tunnel is built elsewhere, and we lose the passage here forever.

Yours. J. F. JOY.

ALEX. LEWIS, Esq., Mayor, City.

P. S.—Such a tunnel would involve the removal of a vastly larger amount of earth than the tunnel once begun, and in circumstances of vastly greater difficulty. It would therefore be very much more expensive than that, if its construction be possible.

To this letter Gen. Smith rejoined that he had, upon two occasions, requested Mr. Joy to examine his plans, but the latter had refused to do so, and he thought Mr. Joy erred in pronouncing them visionary, especially as he had no knowledge of what they were.

Mr. Frederick Broughton, general manager of the Great Western Railway, thought that the best method of proceedure was to first consider where the money was coming from. The previous attempt had been given up by the railway companies for lack of funds. If the citizens of Detroit would now join hands with them, he thought the tunnel could be built. It would, in his opinion, cost not less than $3,000,000, and the Great Western Railway Company would do their share in conjunction with the people of Detroit.

W. K. Muir said that railroad companies were loth to bind themselves to enter into any new project without knowing something about the cost. In these days of cheap transportation, with toll to pay over the Detroit and Niagara Rivers, the question was,—Would it mean $3.50 a car, or, as now. 30 cents? It was also remarked by another gentlemen that, unless they could succeed in getting the railroad companies interested, they might as well give up for the city of Detroit had no power to do anything beyond granting a franchise.

So far as we understand Gen. Smith's proposal, he offers to build a tunnel and to receive his pay only when it is completed, the price to be fixed in advance. If the price is reasonable, the proposition looks very fair, and, from what we know of the engineer's ability, we should be pre-disposed to let him try his hand. There is no doubt that a tunnel with a moderate tariff would be of great value to the railroads centering at Detroit, and of most decided advantage to that city. Sooner or later the means of communication between the two shores will be improved. Detroit does not want a bridge, and a tunnel elsewhere will be very damaging in diverting the business which now passes through her borders.

TESTIMONY ON THE ASHTABULA DISASTER.

We occupied so much room in our last issue, by the insertion of the two letters inspired by the Ashtabula disaster, that we will only take space this week sufficient to give a synopsis of the more important portions of additional testimony taken at Ashtabula and Columbus.

Albert Congdon former master mechanic, who had charge of the shop at which the iron of this bridge was put together, testified before the Legislative Committee that the bridge had been intended for a single track. This statement we do not remember to have seen before, and should doubt whether Mr. Congdon was rightly informed; for Mr. Tomlinson, the engineer first in charge would have so stated, if it had been the fact. Mr. Rogers, in testifying before the Committee, adds some statements which we have not given before. He had charge of the putting up of the bridge. In the first place the upper cords of the bridge were too long and they were shortened by planing down the lugs on the brace blocks. The bridge was then put up, but it immediately settled down to almost a straight line. It was then raised up and shims were put in which lengthened the upper chords three and a half inches. The bridge was again let down by knocking out the wedges slowly, but still would not bear its own weight. A second time it was packed up and new wedges put in it, and this time it stood firm and strong.

The engineer of the Canton Bridge Company, having made a further examination of the bridge was recalled before the coroner's inquest. He considers the system of lower lateral bracing employed as insufficient. He thinks the bridge was not as strong to resist lateral motion as it would have been had the track been on the lower chord, instead of the upper, for the reason that there were no laterals from the top angle block to the abutment. Its being a battered-end truss, he thinks the lateral braces and tension rods should have been attached at some point on the lower chord.

James Doran trackmaster, says that a double track was laid across the bridge when it was built but that only one was ordinarily used, until within four or five years; he had never found the rails on the bridge much out of line; he examined the track east of the bridge the morning after the accident, and found no evidence of the train having left the track. There are guard rails the whole length of the bridge.

Job Abbot, vice president of the Canton Bridge Company, testified at the inquest that he found that the tension members had ample section, and in fact were considerably heavier than necessary for safety, and that the compression members were deficient in section. He is of the opinion that the bridge had become gradually weakened by use, the form of construction being such that many of the compression members were strained over their safe working capacity.

Mr. A. H. Howland, a civil engineer from Boston, who examined the wreck, testified before the coroner that the structure was imperfect in many respects. He found evidence that the I beams of the top chord in the south truss was bent toward the south at a point about twenty feet from the west end of the truss. The wooden floor system was such that it could not be depended upon to give lateral support to the bridge. He considers the whole system of lateral bracing a very defective point in the bridge. In his opinion it was a serious defect in the bridge that the compression members depended, to a great extent, upon their function for retaining their proper position. [We take it that this is intended to mean that it was a fault that the braces were kept in place upon the angle blocks simply by the friction which would arise from their thrust.]

Geo H. Carpenter was also examined and testified at Ashtabula that at the time the bridge was built he was employed in the Lake Shore shops at Cleveland, but afterward had charge of the raising of the bridge, with Mr. Rogers, under his directions. When the braces was sent from the shops to the bridge they had no marks on them to show where they belonged. After the bridge was erected, Mr. Stone expressed himself well satisfied with the work, and said it had been well done. Witness did not consider the system of lateral bracing in the bridge good for anything.

Of course much of the testimony of railroad hands and others, which has been taken, is only valuable so far as it relates to matters of fact and not to matters of opinion. Judgments as to the strength of various parts, and the theories which are offered since the accident, have more or less weight according to the source from which they come. We have been surprised, as we look over the public prints, to see what strange suggestions are thrown out by persons who feel called upon to theorize upon this subject. Most of them are not worth refutation nor reproduction for the readers of the NEWS. We were surprised to see that Mr. Stone in his testimony before the Legislative Committee, stated that carrying floor timbers on the upper chord at other points than joints did not affect the strength of the chord materially. He has been called a bridge builder of great experience, and certainly ought to be well informed on that point. We will close with the abstract below. Magnetism, low temperature, crystallizing, etc., do not seem necessary, in order to account for the sad result.

COLUMBUS, O., February 1.—B. F. Bowen, Thos. H. Johnson and John Graham, civil engineers employed by the Legislative Committee to investigate the Ashtabula railroad disaster, have submitted a sworn statement of facts ascertained by them. After referring to their calculations on the relative strength of different parts of the bridge, and their observations at the wreck they submit the following conclusions:

First—That all the tension members had very large factors of safety, and were abundantly able to sustain all the strains that could possibly come upon them in this bridge.

Second—That all the compression members, except the counter braces were deficient in capacity, having very small factors of safety.

Third—Considered with reference to the location of the break, it appears that the weakest point in the braces was at and near the break, and that the weakest point in the top chord was at the center, though the top chord at the point of failure does not show a state of security much greater than that of the braces. The probability is that the braces failed first, and thereby involved the failure of the top chord also. But inasmuch as both members were weak and were involved in the break, it is of little importance which member took precedence in the failure. The factors of safety throughout the compression members were so low that failure must have followed sooner or later.

At this point the engineers proceeded to say how the failure might have been prevented at a moderate cost. The remainder of the sworn statement of the engineers is devoted to a consideration of other defects in the bridge. While these defects were not directly the cause of the failure they were such as might, in themselves, have led to it. They further add that the material, so far as they were able to judge, was of superior quality, and with few exceptions the workmanship was very superior. In conclusion, they say that they find nothing in the case to justify popular apprehension that there may be some inherent defect in iron as a material of bridges. They find no evidence of any weakness in this bridge which could not have been discovered and prevented.

THE President has recently sent a message to Congress, calling their attention to the necessity of continuing the board for testing iron and steel, and recommending a small appropriation for that purpose. The value of experimental knowledge is referred to, and the Ashtabula bridge is cited as an example where a better knowledge of iron might have averted a calamity.

A report upon Rapid Transit for New York city has been made by Messrs. W. J. McAlpine and E. L. Viele, in which they unqualifiedly condemn elevated roads for steam cars, and characterize the one already in operation in that city as a dangerous experiment. Still, the Gilbert Elevated Railway is doing a fine business, and solving the problem of rapid transit, while the other schemes are yet being debated upon.

THE *Scientific American*, for Jan. 20, contains an interesting article on Rope Gearing, meaning the substitution of ropes for belts or toothed gears for the transmission of power, and refers to two papers, one by Mr. James Durie, read before the Institution of Mechanical Engineers, at Manchester, England, and the other by Mr. K. Keller, published in the *Zeitschrift des Vereins der Deutscher Ingenieure*.

ANY apprehensions of danger from the rapid melting of the great quantity of snow on the ground in this vicinity have, happily, passed away. In the streets of Chicago "mud-time" has prevailed of late very decidedly, but our excellent sewerage system has conveyed away the surplus water most effectively, and a few more days of the labor of the street cleaning brigade, will remove a large part of the accumulated filth of the past months, and give to the city a much more presentable appearance.

THE annual meeting of the Poughkeepsie Bridge Company was held on January 3d, when the treasurer made a satisfactory statement in regard to the payment of the first assessment of ten per cent., or $100,000. Mr. Rust, of the American Bridge Company, reported that the preliminary work was being pushed forward rapidly; that one caisson was ready for launching, others were in progress, and that the company expected to build all four of the piers in the channel up to at least twenty feet above highwater before the close of navigation next fall.

THE *Manufacturing and Trade Review* of Cleveland, one of the most flourishing and prosperous of class journals, if one may judge from its advertising columns, at the beginning of the present year came out with a new and very suggestive heading. As a purveyor of industrial intelligence, the *Review* is second to no other journal in the country.

A SPAN of iron bridge at Kansas City, lately built by the Detroit Bridge and Iron Company, for the Hannibal & St. Joseph Railroad, was tested with a moving load of about 163½ tons, uniformly distributed. Span 175 ft., width 20 ft. height of truss, 27 ft., number of panels 12 original camber two inches. Under the load the deflection at the center was 7⅛ inches, and at the quarters ½ inch. The load being removed, the bridge recovered its original curve.

THE large Cornish engines of the city water works, Louisville, Ky. have steam cylinders 70 inches in diameter and 10 feet stroke. They are double, each working a single acting lift and force pump, 36 inches diameter and 10 feet stroke. The extreme lift, when the river is at the lowest stage, is 21 feet 10 inches. The pump mains have a diameter of 40 inches to admit of the employment of 40-inch pumps, when needed. The highest daily duty was 48,363,344 lbs. of water raised one foot with 100 lbs. of coal; the highest monthly average was 35,957,629 lbs., and the yearly average duty 30,217,365 lbs. Cost of engines and connections complete, 117,753.64.

MR. CHARLES COLLINS, the late chief engineer of the Lake Shore & Michigan Southern Railroad, was born in Richmond, N. Y., in 1826, was educated at an Eastern college, and received his professional instruction at the Rensselaer Polytechnic Institute, Troy, N. Y. He worked for some years in New England, being at one time on the Boston & Albany R. R. He went to Ohio in 1849, took charge of the location of the C. C. C. & I. R. R., and was also employed on the construction. He was next superintendent of the Painesville & Ashtabula road, and, when the Lake Shore and Michigan Southern were consolidated, he was given his late position. During this time he was also more or less connected with some other lines.

THERE has been unusual activity in railroad construction in the State of Ohio. Most of the new lines have been local roads, many of them narrow gauge. The *Railroad Gazette* says that "The roads there seem to be constructed almost wholly from home capital, and largely by those who expect to use them; and this may be said of most of the roads of 1876, even in the newer States. They have been built because their projectors expected profits from their earnings, and not, as were many in 1873 and before, because the projectors expected profits from the work of constructing them." That is a very healthy condition of things, and will lead to a gradual and sound revival of that branch of engineering construction.

IT has been found that granite may be sawed into blocks or slabs, in the ordinary machine, by employing finely divided chilled iron in place of sand. A jet of steam is directed upon a fine stream of melted iron, blowing it into spray, which falls into cold water and is chilled. By using these globules under a saw of soft iron, granite can be sawn at the rate of three or four inches per hour, and for small blocks, where a short saw will bear heavy pressure without buckling, it is found possible to cut 12 or 14 inches per hour. The surface left takes a polish much more readily than does a hammered surface, as there are no bruised and shattered crystals to be ground away.

A chemist has proposed to preserve timber by tanning it with a compound of tannic acid and iron. The resistance of oak to decay has been ascribed to its tannin, and hence this process has been devised. The invention of injecting timber with tannate of protoxide of iron is due to M. Hatzfield; the Eastern Railway Company of France has experimented with it on sleepers. The wood is turned black. The lapse of time only will prove whether the process is worth anything or not. Boucherie, the well-known inventor of the sulphate of copper treatment, denies the efficacy of this new application, contending that salts of iron have yielded only partially successful results.

THE meetings of the Civil Engineer's Club of the Northwest are becoming more interesting each month; the number of members and visitors in attendance, and the subjects presented have largely increased, and with them the opportunities for acquaintance and interchange of opinions on various important undertakings. There is evidence of this same interest being manifested in the other Engineering societies of the country, and we consider it a sign of their recognition as being the nuclei around which the profession must gather in order to concentrate its influence and make itself felt as the great civilizing power in society, and the agency for carrying out those wonderful public improvements which are the marvel and boast of the present century. It is not an easy matter at first sight for engineers to see the utility of these associations, at the meetings of which they may never find it convenient to be in attendance, but if we look at the mass of valuable information that has already been given to the world by the leading Engineering societies of Europe and America, and the opportunities for the discussion of subjects pertaining to the benefit of every member of the profession, besides the many important investigations which they have been instrumental in promoting, we cannot but feel certain that American engineers will very soon see the merit of massing their forces under the leadership of these societies.

This subject of societies reminds us of the query of a correspondent, made some months since, as to whether an organization similar to that of the Engineers' Club might not be effected by the surveyors of this and adjoining States. We think the idea is a good one and very feasible, and we would like to see it carried out. There are a variety of subjects of general importance to both the public and the surveyors that need to be discussed to ensure intelligent action thereon, and we know of no better way than holding meetings at stated intervals for the purpose of a better acquaintance, and a personal interchange of opinions. The subjects might be previously arranged and circulated in printed form among members, so that all attending the meetings might come prepared to take an active part in the discussions. Local or district societies might be formed which would gradually extend over the whole country, holding monthly meetings, and from these clubs State societies might be constituted around which would crystallize the scattered influence of the local clubs, and which would bring together in an available shape the practice of the best surveyors in the State, so as to produce uniformity therein, and give it that sanction in legal proceedings that could not be overturned. This State Society, meeting once or twice a year, or even quarterly, would soon combine the best talent in the State and when any legislation was to be had, it would undoubtedly control it. By a combination of these societies, throughout the public land states, measures of reform in surveying practice can be organized and carried out that never can be otherwise, and the profession of surveying might be given a recognition that it never will attain to while it is practiced after the present isolated mode. Correspondence on the subject of Surveyors' Societies for any part of the Union will be in order and we will be pleased to give such as much of our available space as we can spare.

FROM the Annual Report of the city of Middletown, Conn., for the year ending January 1st, 1877, just received, we make the following extracts. The Mayor in his address says:—

"The question of 'how to do it' in relation to the Street Commissionership has been experimented upon for years by successive City Councils, and is not yet determined, though it has often resulted in illustrating to the satisfaction of our citizens 'how not to do it.' We would suggest that after electing a competent man for the position, that he be paid a living salary upon the inexorable condition that his time be devoted to the business of the Street Department and that exclusively, and not be allowed to engage in other occupation, neither upon *contracts* for individuals in city work nor for his personal benefit."

Also in relation to the sewerage "much expense has accrued to this department from the inefficient manner in which certain branches of our sewerage had been constructed under the original contract, which is the result of what was then bad faith, or gross negligence. To save our streets, this work had to be gone over again in the proper manner, and of course the expense followed."

The Street Committee evidently had a bad time of it as their Report is a series of groans over the total depravity of human nature by which their own labors and the city expenditures have been greatly increased in the past year.

The Sewer Committee, at the beginning of the year, "guessed" that the expenditures for sewers would fall

within one thousand dollars, which was just $4,409.35 out of the way, a result which was largely due to their being obliged to overhaul a great deal of dishonest work of former contractors and rebuild it at a largely increased cost.

The Engineers' Report refers mainly to the streets, of which 3010 lineal feet were graded, and 22,040 sq. feet of flagging laid; the total expenses were $11,474.55 of which $591.67 was salary of Commissioner and $303.90 was for engineering.

THE subject of heating street cars in cold weather has been attracting attention in several of the larger cities, and notably in New York. From the *City Record*, an official paper, we learn that the committee to whom the subject was referred has reported:

"That the subject so referred received the closest attention of your Committee, several meetings having been held, and all persons interested for and against the measure were afforded every possible facility to make their wishes known.

"At the outset, your Committee were induced to believe that the question was one of more than ordinary importance; that our entire community, at least that portion of it that used street cars in travelling to and from their places of business, or for other purposes, were unanimously in favor of compelling the several companies to heat their cars, and that but one sentiment pervaded our people, and that favorable to the proposition. In this, however they were greatly disappointed. At the meetings of your Committee but two classes of persons appeared: One, the officers of the several companies; the other, inventors of apparatus for heating the cars. Both classes were directly and pecuniarily interested. Not one disinterested person, not one citizen other than those above referred to, appeared before your Committee in advocacy or in opposition to the measure.

"From this it is clear to your Committee that the general public are totally indifferent, and care not what action your Committee take in the premises. Indeed, from inquiries made by your Committee, of persons who daily use the cars, they are convinced that the travelling public are averse to the measure, being apprehensive that a crowded car, overheated by artificial means, in addition to the natural heat or warmth of the body, would superinduce disease, and that the seeming comfort of a heated car would be more than offset by the fear of contracting disease.

"Your Committee, therefore, are of the opinion that it is not advisable, at this time, at least, to exercise the power, and compel the heating of the city railroad cars. So many contingencies connected with the health of the passengers constantly present themselves to the minds of your Committee, that they believe the question can be with safety left to the care of those charged directly with the preservation of the health of the public.

"One or two regulations connected with the running of the city railroad cars, however, can, with advantage to the public, be insisted on. The front door of every car should be securely fastened, and never opened from the time the car starts until it reaches its destination; clean straw should be provided every day, for the bottom of every car, and the ventilation should be so arranged that impure air could be permitted to escape from the car by some arrangement that will at the same time prevent the admission of cold air."

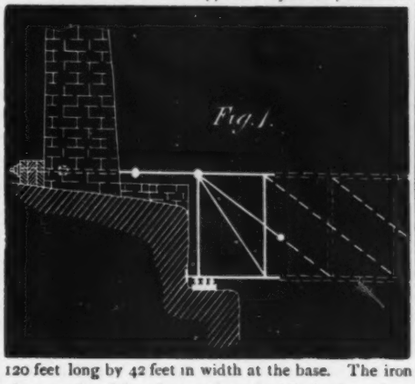
A minority report, however, asks that the experiment of heating be tried on ten per cent. of the cars running in New York city so that intelligent action may be taken hereafter in the matter.

THE KENTUCKY RIVER BRIDGE.

About twenty-three yerrs ago, the late John A. Roebling commenced a work which, if completed, would have been the crowning triumph of his life. It was a railroad suspension bridge of 1,236 ft. span, crossing the canon of the Kentucky river 275 feet above the bottom of the gorge. The towers were built and the anchorages finished, but at this stage of the work the railroad company failed. Roebling was stopped, and until the engineers of the Cincinnati Southern railway decided that no better crossing than Roebling's location could be found, the giant piers stood in a deserted wilderness, a monument to the financial crash of 1857.

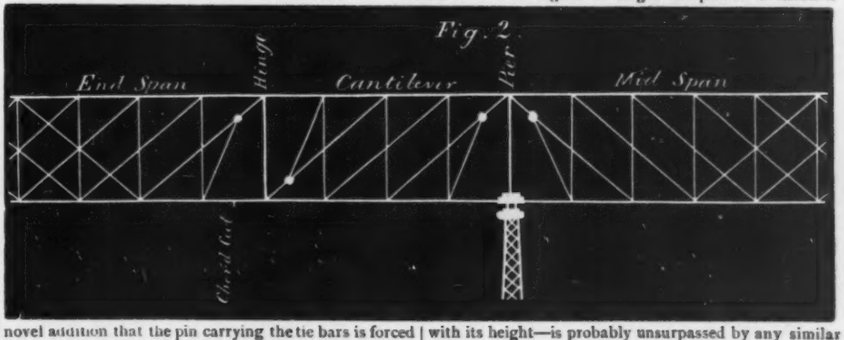
When Cincinnati decided to build a railroad to Chattanooga, the gorge of the Kentucky was found to be one of the worst obstacles on the route; and when bids on this crossing were called for, each competitor was required to make up his own plan for the entire structure, which plan it was obligatory should meet the difficulties attendant upon the following conditions of the case: First, the erection of a structure over a chasm 275 feet deep; next, in connection with this fact that the rise and fall of the river was 55 feet, and that it had been known to rise 40 feet in a single night, and generally averaged a flood every two months. Lastly, the river makes a bend just under the bridge, which renders its passage by steamers and rafts too hazardous to permit of the erection of a pier in the waterway.

A number of meritorious plans were presented, but the one finally accepted was that prepared by Mr. Shaler Smith, of the Baltimore Bridge Company. The viaduct as now being constructed, consists of three spans, of 375 feet each, resting on the bluffs and on two iron piers, which latter in turn are supported by stone piers, each



120 feet long by 42 feet in width at the base. The iron piers consist of four legs each, and while having a base of 71 ft. 6 in., by 28 ft., their longitudinal profile terminates in a point at the top, or rather in a 12-inch pin, upon which the truss rests as on a rocker. The entire pier is a complete structure within itself, and can be rolled about on the masonry, the pedestals resting on double roller beds for this purpose.

The truss itself is, during erection, a continuous girder, of the Whipple type; but after erection it will be converted into one continuous girder, 525 feet long, projecting at each end 75 feet over its points of support, and carrying from each of these cantilevers a 300-feet span, which bridges the distance from the end of the cantilever to the bluff. It was necessary to make the bridge a continuous girder in order to raise it without false work; and the hinges were obligatory because the rise and fall of the piers from thermal changes will amount to fully two inches, and would vary the strains hourly, in a true continuous truss. The truss is 37.5 ft. deep, and 18-ft. wide, and each bay is divided into 20 panels of 18.7 ft. each. All connections between ties, posts and chords are hinged on pin connections, but the chords are riveted to each other throughout, with the



novel addition that the pin carrying the tie bars is forced into the chord splice by hydraulic pressure, and thus does duty as a rivet. It will be seen that the details combine both the American principles of pin joints and of massing the materials in approved shapes along the lines of strain, together with the European practice of continuous riveted chords, fitted to resist both tension and compression. This peculiar mode of construction was adopted in order to erect the truss in the manner which we are now about to describe.

After the bridge seat was cut out of the cliffs, the end posts were set up, and the first section of bottom chord laid in place, each chord being continued back to the rock by a large screw-jack placed between its rear and the face of the bluff. Then the top of each end post was bolted back to Roebling's towers by anchor bolts, which had a screw adjustment. From this point the end or main tie was carried to the bottom chord at the foot of the second post, and then post No. 2 and the first panel of top chord were put in place. When the first panel was in position, the work looked as shown in Fig. 1. It will readily be seen that with these connections once made, the structure could be built out, panel by panel, until the limit of strength of the anchorage bolts, or of the top chord, or the available resistance of the Roebling towers had been reached. This last was the governing factor, and the other parts were proportioned to suit. Accordingly, as the truss grew out from the face of the bluff, a temporary wooden tower sprang up from the bottom of the valley to meet it, the center of the tower being 196 ft.

The next flight was to the permanent pier, 178 ft. 2 in. When the span left the bluff the iron pier was started upward from the masonry, and the two met in mid-air, the working forces on each arriving at the point of junction within two hours of each other. The weather was cold, and the span was short, owing to the compression of the lower chord and the effect of temperature; but this had been foreseen, and the huge pier, weighing 400,000 lbs. was moved on its rollers towards the span until the pier which connects the two could be put in place. This done, the truss was built out as before until the middle of the river was reached, which completed the work from the north side. In the meantime the temporary wooden tower had been taken down, and at this present writing the same process just described is going on, but from the south side of the river.

When the two halves of the bridge meet, in the centre of the middle span, the two projecting half-spans will be adjusted to the same level by loading the shore spans, and the connecting sections of chord put in place. The last operation will consist in taking out the bottom chord pins in the fourth panel north and south of each pier in the shore spans, thus hinging these two spans and fixing arbitrarily and without ambiguity the strains in all parts of the truss. In order that there may be no doubtful action at the hinging points, both web systems are concentrated into one in the two panels adjoining the post at which the chord is cut, as shown in fig 2.

This is also done in the end panels of each span in order to concentrate the shearing strains more conveniently. In erecting this bridge the most important points for computation were: first, the angle to be given the span at starting so as to land properly on the wooden pier, and, next, the correct elevation to be given to the truss at the wooden tower so that an exact junction could be made with the pin on the top of the permanent iron pier. These operations were both successful.

Altogether, in the novelties introduced in both construction and erection, and in strict adherence to theory throughout, this great viaduct—the most important in the world in regard to length of span in connection with its height—is probably unsurpassed by any similar work now existing. When it is completed, we hope to publish a plate and full description.

The engineers who decided upon Mr. Shaler Smith's design as the best were Mr. Thomas D. Lovett, then Consulting Engineer of the Cincinnati Southern, and Mr. G. Bouscaren, who has since succeeded him in that position. The iron work was all done by the Edgemoor Iron Company, and it was watched and inspected from the rolling mill pile to the finished bridge, pieces being tested out of every plate used. The modulus of elasticity was obtained for every individual eye-bar, and the bars were paired together according to their moduli. Messrs. C. C. Wrenshall, Charles Houser and Michael Walsh are the superintendents in charge of the erection, and the engineers on the part of the railroad company are Messrs. Rudolph Weiser, Charles Lasker and Chas. Bates. The erection was begun Oct. 16 and will probably be completed about Feb. 20. There are 2,855,000 lbs. of iron in the spans, and 793,000 lbs. in the piers and the amount of masonry is 12,915 cubic yards. The spans have iron stringers as well as floor beams.—*Railroad Gazette.*

CIVIL ENGINEERS' CLUB OF THE NORTH-WEST.

The 72d regular meeting of the Club was held at the Sherman House Club Rooms, Chicago, on the 6th of February, beginning at 4 P. M.

The President, Mr. E. Chesbrough, occupied the chair.

The minutes of the January meeting having been read and approved, Mr. L. P. Morehouse, the Secretary, reported the receipt from Colonel Farquhar, U. S. A., of St. Paul, of the "Annual report upon the preservation of the Falls of St. Anthony, and the improvement of the Mississippi and Minnesota Rivers," and the "annual report upon the improvement of the Lake Superior Harbors."

The receipts of documents from General A. A. Humphreys, Chief of Engineers, U. S. A., published by the War Department, on "Internal Improvements" was also acknowledged. A vote of thanks was then given to the donors.

Mr. W. B. Rice exhibited a new pontoon draw-bridge, and explained briefly the workings of the same.

Mr. F. W. Clarke contributed and read the paper for the evening upon the "Artificial Drainage of the Calumet Marshes."*

Mr. J. M. Emmerson exhibited a model of a floating lighthouse, by the late Capt. Moody of London. He gave a very interesting account of its history and also the experiments already tried with it, both its adaptability for the purposes of a lighthouse, and as built for a floating battery.

The meeting then adjourned.

CIVIL ENGINEERS' CLUB OF ST. LOUIS.

The one hundred and seventy-third meeting of the Civil Engineers' Club of St. Louis, was held January 24th, 1877, at Washington University, St. Louis. Meeting called to order by the President. Minutes of last meeting read and approved. Secretary reported progress in the matter of preparing Dr. Kluepfel's paper for publication.

Mr. Robert Moore then read a paper on "Force and Momentum," being a criticism on an article by Prof. De Volson Wood in the January number of Van Nostrand's Engineering Magazine. Moved, the thanks of the Club to Mr. Moore for his able and instructive paper.

Prof. Woodward then read extracts from a report on bridging the Mississippi at St. Louis, by Chas. Ellet, Jr., published in Philadelphia, in 1840. The Club then examined one of Crooke's radiometers, which belonged to the University. On motion adjourned.

CORRESPONDENCE.

HENDERSON, KY., *Feb. 3rd, 1877.*

EDITOR ENGINEERING NEWS:

SIR:—In reference to the subject of correspondence of X, in No. 3 of this volume, the reason why the pump failed to draw water, was owing to one or the other, or probably both, of two causes. First, that the suction pipe received air somewhere along its length; and second, that the pump was in an imperfect condition. For should the pipe have been tight and the pump in good condition, the water must surely have continued to flow; though it is to be borne in mind, that the velocity of the pump should only have been such as to have accommodated its displacement to the retarded flow of the water through so long and small a suction pipe. In practice, however, it is hardly to be expected that such perfect conditions could well exist, or could be maintained under the circumstances as to give satisfactory results. A.

—We regret to find Gov. Robinson lending his countenance to a movement designed to abolish the State survey established last year, a bill for that purpose having been introduced at Albany. We are the more surprised because the advantages of the survey are not in question, while the urgency of it is placed beyond all doubt by the Report of the Commissioners transmitted to the Legislature last month. That the wealthiest and most populous State of the Union, and one of the oldest, has never been surveyed "since the pioneer surveyors ran their compass lines through the woods, without taking into consideration the ever-changing variation of the magnetic needle, and measured the distances with chains of unknown lengths," seems incredible enough; but it is not half so incredible, nor, to speak plainly, half so disgraceful, as that any State official should desire to interrupt for a single day the geodetic labors already so auspiciously begun. Mr. James T. Gardner, the director of the Survey, reports a simply deplorable condition of local surveys, county boundaries and landmarks, and vast popular ignorance of the topography of the State. Examining the boundaries of eleven counties, he found only two out of more than sixty corners marked with any authentic monuments. In the western part of New York important lines were made the centres of the roads, but the shifting of fences has since then rendered the exact centre indeterminable, and has brought uncertainty and confusion into the local surveys based upon it. Trees, stakes, and other perishable landmarks having become obliterated, the only dependence of litigants is upon the recollection of the oldest inhabitants. Adjacent towns, in doubt as to their common boundary, often compel a railroad to pay double taxes on the same piece of track. As for the construction of railroads, "there is ample proof," says Mr. Gardner, "that if the people of the State had possessed a topographical map such as any European country has, the impracticability of running the Oswego Midland Railroad could and would have been clearly demonstrated before the building of the road, and $20,000,000 saved to the people of the State." Our best maps, however, contain errors like these: Albany placed about a mile from its true position, Hamilton College two miles, Ogdensburgh half a mile, Syracuse one and a half, Elmira two to three, Buffalo and Plattsburgh three. And these maps are very dear! It seems, however, a waste of time to adduce proofs of the crying need of an authoritative triangulation of the State, connected with that of the Coast Survey already executed in the valley of the Hudson. Mr. Gardner estimates that in ten years, at $20,000 a year, the whole State can be furnished with Survey stations that will last for ever. Will anybody deny that the State could better divert $200,000 from its unfinished Capitol than grudge the money to this indispensable work?—*The Nation.*

*This paper is printed in full on page 41.

THE UTILIZATION OF FURNACE-GAS.*

BY GUSTAV KLUEPFEL

In every furnace, where smelting material and fuel are charged in alternate layers, the inevitable consequence is, that the escaping gas contains a certain quantity of carbonic oxide, because the immediate product of combustion, carbonic acid, meets, on its way through the furnace, the carbon of the fuel at such a temperature, that it must unite with it and form carbonic oxide. This chemical truth can also be expressed in the following words: In furnaces of the character mentioned, it is theoretically impossible to make use of all the available heating effect of the fuel, the difference being contained in the escaping gas.

Mr. I. Lowthian Bell, in one of his latest papers, read before the English Iron and Steel Institute, states in detail that even in the most complete and best conducted blast furnaces of the Cleveland district of England, a little more than one-half the available heat condensed in a blast-furnace is contained in the escaping gases. But in most cases the latter proportion is much larger.

Happily for the production of pig iron, there is a demand for fuel outside of the furnace, which can be supplied by the escaping gas. This demand is so great, that, as Mr. Bell states in that same paper, those furnaces which retain not more than one-half of the available heat in their gases, are obliged to use the most improved apparatus for generating and supplying steam, to supply their need. But generally the proportion is such, that the supply is much greater than the demand. This is particularly the case where the fuel is partly or altogether raw coal.

It is but a short time since all the heating force contained in the escaping gas was a dead loss, as steam-engines and hot blast stoves were heated with coal; but even now that almost every blast furnace uses furnace gas, there is seldom much care taken in the utilization of this gas, and very often the greater part of it is lost before entering the place where it is wanted. Little can be said against this practice, where the supply of furnace gas is really much greater than needed. But the fact is, that almost invariably the gas is scarce, if the furnace itself is conducted with care and with the aim of saving fuel.

In the last ten years much progress has been made in reducing the amount of fuel used in the furnace itself, and to effect that progress a great amount of capital has been spent, particularly in making the blast furnaces higher, and by building expensive hot blast stoves. The consequence of these improvements has been in the first place, that a greater pressure of the blast has been found necessary, and therefore also a greater amount of steam was needed; in the second place, the hot blast stoves have got a greater surface, and therefore they needed more heating. All these improvements have augmented the amount of fuel required outside of the furnace, which makes it plain, that the very furnaces which are not advanced in their metallurgical standard, complain about scarcity of furnace gas, and have to burn coal in addition.

To avoid the latter expense a good many improvements in different modern furnace plants have been made. In the first place, the constructors of machinery for blast furnaces have tried to reduce the amount of steam needed for the blowing engine, and the most modern blast furnaces, in Grmany and Belgium especially, derived much advantage from the use of the best kind of condensing engines. At the same time, boilers of more complicated and effective types, have been put in operation, and the use of superheated steam introduced with some advantage. But all these improvements have been made at the cost of simplicity, so desirable in work of that kind, where water is very impure, and where no stoppage is permissible.

A second kind of improvement has resulted from the study of the combustion of the furnace gas. Even the richest furnace gas consists of only about one-fourth by weight of carbonic oxide, and especially if it contains a good deal of moisture, there is some difficulty in burning all the gas introduced into the hot blast or into the boiler stove. Now it is true, that regarding hot blast stoves, the practice of introducing gas is, as a rule, much better in American than in the majority of European works, because the gas here is always burned in a very solid combustion chamber, where the heat is so intense that no particle of the gas can pass unburned. As for boiler stoves it is clear that the same principle can be applied, yet it is seldom done. In the Meier Iron Works, combustion chambers have been built in front of the boilers, and the air for burning the gas is first heated by passing through flues made in the side walls of said chambers.

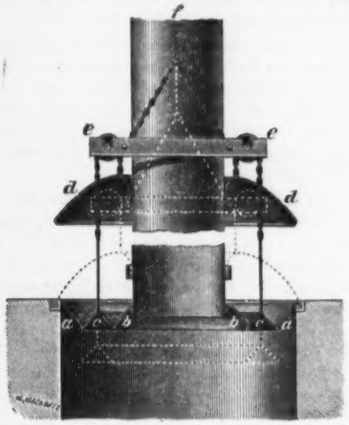
Another great loss of heat is caused by the hot blast stoves of whatever construction they may be. The stoves supplied with iron pipes lose the larger part of the heat they receive through the chimneys; in the Whitwell stoves this loss is avoided, the temperature of the escaping gas being no more than 200° Centigrade, but in using these stoves a considerable loss takes place by the radiation of the very large external surface. In case this loss should prove injurious, I propose to cover the whole surface of the stoves with a thin layer of slag-wool, which could easily be secured by means of wooden slats fastened by wire.

The improvements spoken of all relate to the better utilization of the gas conducted to the several places of combustion. But there is another possibility of saving which has received until recently very little attention on the part of ironmasters. I refer to the loss of gas escaping during the time of charging the furnace, which is very considerable in modern blast furnaces, where the number of charges is now much greater than it used to be a few years ago, and where on account of economy of labor one man has to do all the filling work, and therefore the furnace is open about half the time. Aware of that fact I considered the introduction of the charging apparatus of Weimer & Birkinbine, which was exhibited in full size at the Philadelphia Exposition as a great improvement. In this apparatus the cup and cone applied in the usual way are covered by a cast iron bell, in which openings appear by means of a rotation of the bell. Therefore, whenever a blast-furnace is built to fit a cup and cone apparatus, I would strongly recommend Weimer & Birkinbine's improvement. But there are objections to the cup and cone, at least for a new furnace, which according to the latest theory and experience should be built with a wide top in order to have as much contents as possible. For such a furnace the cup and cone as well as the covering bell would become uncommonly heavy and expensive, or if made smaller the distribution of the charge would not

* A paper read before the Engineers' Club of St. Louis, Dec. 6th, 1876.

be done in the best way. Besides that much can be said in favor of a wide perpendicular pipe as the first receiver of the gas, which makes the dust carried along fall down into the furnace. Taking this in consideration I designed for the blast-furnace of the Meier Iron Company the charging apparatus shown in the accompanying sketch.

The receiving pipe in the centre of the furnace top is supported by two inclined pipes, resting upon the platform. The cone *a a*, made of boiler iron and stiffened



with angle iron is fixed to the furnace wall and a similar cone *b b* is fixed to the receiving pipe, both made in sections in such a way that they can be gradually removed if worn out. The conical ring *c c*, also made in sections, is suspended by four chains, terminating on one end in gas pipes a little thicker than the chain and on the other connected with the sheet iron bell *d d*. Those chains rest upon four pulleys fixed in a frame *e e*, which is suspended on both sides of the central receiving pipe from one end of a double plate iron lever *f*, whose further end is controlled by a rod connected to a hydraulic piston below, which can be managed from above. The weight of the bell *d d* is regulated in such a manner, that it balances not only the weight of the conical ring *c c* but also the weight of that part of the charge, which rests upon that ring. Now, when the frame *e e* attains its highest position, the furnace is closed by the ring *c c* and the charge can be made and equally distributed without haste and without the least loss of gas, after which the valve of the hydraulic apparatus is opened, the bell descends leaving the furnace closed by the conical ring *c c* until the bell reaches the platform, when its weight is taken up and the conical ring descends further until the frame *e e* has reached its lowest point and the charge falls into the furnace during which time the furnace is closed by the bell. Reversing the process the bell cannnot rise until the ring *c c* has closed the furnace.

In that way we have a self-acting double closed top, which in whatever position prevents the gas from escaping. At the same time the filler can take his time and it can easily be seen, whether he distributes the charge equally all round as he ought. The charges will get a conchoidal shape, deeper in the centre and higher on the circumference. This will help to a more equal distribution of the gases through the furnace, because without such a precaution they are inclined to pass faster near the walls than in the centre of the furnace. Another advantage of this apparatus will be, that there are no horizontal flues, or gas-pipes where dust could accumulate.

SURVEY OF THE PUBLIC LANDS—HOW TO TELL TOWNSHIP AND SECTION CORNERS.*

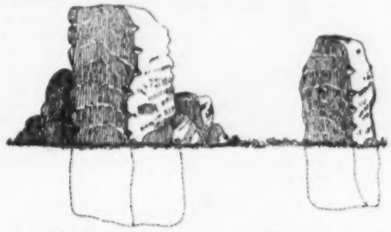
(*Concluded from page 34.*)

From quarter section and meander corners two bearing trees are to be marked, one within each of the adjoining sections.

Where the requisite number of "bearing trees" is not to be found at convenient and suitable distances, such as are found are to be marked as herein directed but in all such cases of deficiency in the number of bearing trees (unless, indeed, the boundary itself be *a tree*), a *quadrangular trench*, with sides of *five* feet, and with the angles to the cardinal points, must be spaded up outside the corner, as a center, and the earth carefully thrown on the inside, so as to form a range of earth, which will become covered with grass, and present a small square elevation, which in after-time will serve to mark unmistakably the spot of the corner.

CORNER STONES.

Where it is deemed best to use STONES for boundaries, in lieu of posts, you may, at *any* corner, insert endwise into the ground, to the depth of 7 or 8 inches, a stone, the number of cubic inches in which shall not be less than the number contained in a stone 14 inches long, 12 inches wide, and 3 inches thick—equal to 504 cubic inches—the edges of which must be set north and south, on north and south lines, and east and west, on east and west lines; the dimensions of each stone to be given in the field-notes at the time of establishing the corner The kind of stone should also be stated.



TOWNSHIP CORNER STONE. SECTION CORNER STONE.

MARKING CORNER STONES.

Stones at township corners, common to four townships, must have *six* notches, cut with a pick or chisel on each edge or side toward the cardinal points; and where used as section corners on the range and township lines, or as section corners in the interior of a township, they will also be notched, to correspond with the directions given for notching posts similarly situated.

Posts or stones at township corners on the base and standard lines, and which are common to two townships on the north side thereof, will have *six* notches on each of the *west*, *north*, and *east* sides or edges; and where such stones or posts are set for corners to two townships *south* of the base or standard, *six* notches will be cut on each of the west, *south* and east sides or edges.

Stones when used for quarter section corners, will have ¼ cut on them—on the west side on north and south lines, and on the north side east and west lines.

QUARTER SECTION CORNER STONE. SECTION CORNER.

MOUNDS.

Whenever bearing trees are not found, mounds of earth, or stone, are to be raised *around posts* on which the corners are to be marked in the manner aforesaid. Wherever a mound of earth is adopted, the same will present a conical shape; but at its base, on the earth's surface, a *quadrangular trench* will be dug; by the "trench" (here meant) is to be understood a *spade deep* of earth thrown up from the four sides of the line, *outside* the trench, so as to form a *continuous elevation along its outer edge*. In mounds of earth common to *four* townships or to *four* sections, they will present the *angles* of the quadrangular trench (*diagonally*) towards the cardinal points. In mounds common only to *two* townships or *two* sections, the *sides* of the quadrangular trench will *face* the cardinal points. The sides of the quadrangular trench at the base of a township mound are to be *six* feet, the height of mound *three* feet.

At section, quarter-section, and meander corners, the sides of the quadrangular trench at base of mounds are to be *five* feet, and the conical height *two and a half feet*.

Prior to piling up the earth to construct a mound, there is to be dug a spadeful or two of earth from the corner boundary point, and in the cavity so formed is to be deposited a *marked stone* or a portion of *charcoal* (the quantity whereof is to be noted in the field-book); or in lieu of charcoal or marked stone, a *charred stake* is to be driven twelve inches down into such center point; either of those will be a *witness* for the future, and whichever is adopted, the fact is to be noted in the field-book.

When mounds are formed of *earth*, the spot from where the earth is taken is called the "*pit*," the center of which ought to be wherever practicable, at a uniform distance and in a uniform direction from the center of the mound. There is to be a "pit" on *each* side of every mound, distant eighteen inches outside of the trench. The trench may be expected hereafter to be covered by tufts of grass, and thus to indicate the place of the mound, when the mound itself may have become obliterated by time or accident.

At meander corners the "pit" is to be directly on the line, *eight links* further from the water than the mound. Wherever necessity is found for deviating from these rules in respect to the "pits," the course and distance to each is to be stated in the field-books.

Perpetuity in the mound is a great desideratum. In forming it with light alluvial soil, the surveyor may find it necessary to make due allowance for the future settling of the earth, and thus making the mound more elevated than would be necessary in a more compact and tenacious soil, and increasing the base of it. In so doing, the relative proportions between the township mound and other mounds is to be reserv d as nearly as may be.

The earth is to be pressed down with the shovel during the process of piling it up. Mounds are to be *covered* with sod, grass side up, where sod is to be had; but, in forming a mound, *sod* is NEVER to be *wrought up* with the earth, because sod decays, and in the process of decomposing it will cause the mound to become porous, and therefore liable to premature destruction.

POSTS IN MOUNDS

must show above the top of the mound ten or twelve inches, and be notched and marked precisely as they would be for the same corner, without the mound.

MOUND MEMORIALS.

Besides the *charcoal*, marked *stone* or *charred stake*, one or the other of which must be lodged in the earth at the point of the corner, the deputy surveyor is recommended to plant *midway* between each pit and the trench, seeds of some tree (those of fruit trees adapted to the climate being always to be preferred), so that, in course of time should such take root, a small clump of trees may possibly hereafter note the place of the corner. The facts of planting such seed, and the kind thereof, are matters to be truthfully noted in the field-book.

WITNESS MOUNDS TO TOWNSHIP OR SECTION CORNERS.

If a township or section corner, in a situation where bearing or witness trees are not found within a reasonable distance therefrom, shall fall within a ravine, or in any other situation where the nature of the ground, or the circumstances of the locality, shall be such as may prevent or prove unfavorable to the erection of a mound, you will perpetuate such corner by selecting in the immediate vicinity thereof, a suitable plot of ground as a site for a bearing or *witness mound*, and erect thereon a mound of earth in the same manner and conditioned in every respect with *charcaal*, *stone*, or *charred stake* deposited beneath, as before directed; and measure and state in your field-book the distance and course from the position of the true corner of the bearing or witness mound so placed and erected.

DOUBLE CORNERS.

Such corners are to be nowhere except on the base and standard lines, whereon are to appear both the corners which mask the intersections of the lines which close thereon and those from which the surveys start on the north. On these lines, and at the time of running the same, the township section and quarter-section corners are to be planted, and each of these is a corner common to *two* (whether township or section corners), on the north side of the line and must be so marked.

The corners which are established on the standard at the times of running it, are to be known as "*standard corners*," and in addition to all the *ordinary corners* (as herein prescribed), they will be marked with the letters S. C. Closing corners will be marked with the letters C. C., in addition to other marks.

You will recollect that the corners (whether township or sectional corners), which are *common* to *two* (two townships or two sections), are not to be planted *diagonally*, like those which are common to *four*, but with the flat sides facing the cardinal points, and, on which the marks and notches are made as usual. This, it will be perceived, will serve yet more fully to distinguish the standard parallels from all other lines.

By instructions to surveyor-general, dated June 1, 1864, the Surveying Manual was modified in the following particulars, to wit?

POSTS IN MOUNDS.

All posts in mounds will hereafter be planted or driven into the ground to the depth of twelve inches, at the precise corner point; and the charcoal charred stake, or marked stone required in the Manual will be deposited twelve inches below the surface, against the north side of the post when the deputy is running north, and against the west side when the deputy is running west, etc.

Township mounds will be five feet in diameter at their base, and two and a half feet in perpendicular height. Posts in township mounds are therefore required to be four and a half feet in length, so as to allow twelve inches to project above the mound.

The planting of seeds between the pits and trenches as directed on page 11 of the Manual, is not required.

PITS IN LIEU OF TRENCHES.

The quadrangular trench required in connection with the construction of mounds is dispensed with. The *pits* will be continued, and should be of uniform dimensions. The pits for a township mound will be eighteen inches wide, two feet in length, and at least twelve inches deep, located six feet from the post. At section corners the pits will be eighteen inches *square*, and not less than twelve inches in depth.

At township corners common to *four* townships, the pits will be dug on the lines and lengthwise to them. On base and standard lines, where the corners are common to only *two* townships or sections, three pits only will be dug—two in line on either side of the post, and

* From Copp's Land Owner.

one on the line north or south of the corner, as the case may be. By this means the standard and closing corners will be readily distinguished from each other.

NOTCHING SECTION CORNER POSTS.

Posts or stones at the corners of sections in the interior of townships will have as many notches on the *south* and *east* edges as they are miles from the south and east boundaries of the township, instead of being notched on all four edges as directed in the Manual.

BEARING TREES.

Where a tree not less than two and a half inches in diameter can be found for a bearing tree within 300 links of the corner, it should be preferred to the trench or pit. The *quadrangular trench* required in the Manual as a substitute, where the requisite number of "bearing trees" is not found, is dispensed with, and a *pit* two feet square and not less than twelve inches deep is required in lieu thereof.

The following approved rules for the subdivision of sections are based upon the laws governing the survey of the public lands.

Under the provisions of the act of Congress approved February 11, 1805, the course to be pursued in the subdivision of sections, is to run straight lines from the established quarter-section corners—U. S. surveys—to the opposite corresponding corners and the point of intersection of lines so run, will be the corner common to the several quarter-sections, or, in other words, the legal center of the section.

In the subdivision of fractional sections, where no opposite corresponding corners have been or can be fixed, the subdivision lines should be ascertained by running from the established corners due north, south, east, or west lines, as the case may be, to the water-course, Indian boundary line, or other external boundary of such fractional section.

The law presupposes the section line surveyed and marked in the field by the U. S. deputy serveyors to be due north and south, or east and west lines, but in actual experience this is not always the case; hence, in order to carry out the spirit of the law, it will be necessary, in running subdivisional lines through fractional sections, to adopt mean courses where the section lines are not due lines, or to run the subdivision line parallel to the section line.

Upon the lines closing on the north and west boundaries of a township, the quarter-section corners are established by the U. S. deputy surveyors at precisely forty chains to the west or north of the last interior section corners and the excess or deficiency in the measurement is thrown on the outer tier of lots, as per act of Congress approved May 10, 1800.

In the subdivision of quarter-sections the quarter-quarter corners are to be placed at points equidistant between the section and quarter-section corners and between the quarter corners and the common centre of the section, *except* on the last half-mile of the lines closing on the north or west boundaries of a township, where they should be placed at twenty chains (original measurement) to the north or west to the quarter-section corner.

The subdivision lines of fractional quarter-sections should be run from points on the section lines, intermediate between the section and quarter-section corners, due north, south, east, or west to the lake, water-course, or reservation which renders such tracts fractional.

When there are double sets of section corners on township and range lines, the quarter corners for the sections south and east of the lines are not established in the field by the United States surveyors, but in subdividing such sections said quarter corners should be so placed as to suit the *calculations of the areas of the quarter sections adjoining the township boundaries*, as expressed upon the official plat, adopting a proportional measurement where the present measurement of the north or west boundaries of the sections differs from the original measurement.

RE-ESTABLISHMENT OF LOST CORNERS.

The original corners when they can be found, must stand as the true corners they were intended to represent, even though not exactly where strict professional care might have placed them in the first instance.

Missing corners should be re-established in the identical localities they originally occupied. When the point cannot be determined by the existing land-marks in the field resort must be had to the field notes of the original surveys. The law provides that the lengths of the lines as stated in the field-notes shall be considered as the true lengths thereof, and the distances between corners set down in the field-notes constitute proper data from which to determine the true locality of a missing corner; hence the rule that all such should be restored at distances proportionate to the original measurements between existing original corners. That is, if the measurement between two existing corners overruns or falls short of that stated in the field-notes, the excess or deficiency should be distributed proportionately among the intervening section lines between the said existing corners standing in their original places. As has been observed, no existing original corner can be disturbed, and it will be plain that any excess or deficiency in measurements between existing corners cannot in any degree affect the distances beyond said existing corners, but must be added or subtracted proportionately too or from the intervals embraced between the corners which are still standing.

IRON BRIDGES.

The selection of bridges should be governed by economy and adaptability to location, since no one of the well-recognized types of bridges is better than another. Apart from such motives *any* bridge designed on correct principles is a good one, whether a beam-truss, a suspension-truss, or a bowstring. On the contrary, any one is bad if improperly designed, and the principles of its construction ignorantly conceived. A general rule that will lead to satisfactory results is *to ignore any plan of bridge that can not be accurately analyzed as to the character and amount of strain occurring in all its parts*—such, for instance, as the Truesdell bridge, scores of which have been built during the last fifteen years; and assuming that the great majority are still in use, giving satisfaction to their users, yet their form of construction is one that removes them beyond the pale of the most refined analysis. They are purely empirical structures, and being such their construction should under no circumstances be permitted. It is bordering on criminality to build any structure on a plan that no human being can tell definitely any thing about, when there are so many plans that we thoroughly understand. —*Boller's Practical Treatise.*

RAILROAD NEWS.

Japan is to begin building interior lines of railroad this year.

The people of Eugene township, Vermillion county, Ind., have voted $16,000 to aid in extending the Frankfort & Kokomo road to the State line.

A bill has been introduced in Congress by Mr. Hubbell, chartering a freight railroad company from tide-water on the Atlantic to the Missouri river.

The Longview & Sabine Valley R. R. Co. has been organized in Texas to build a railroad from Longview southeastward. Work has already been begun.

A party of Northern capitalists are talking of building a road from Jacksonville, Fla., southeast to St. Augustine, on the coast. The distance is about forty miles.

A private road for carrying lumber is being built by Messrs. Barret & Roper, from North Landing, in Norfolk county, Va., to Mount Pleasant, seven miles.

Surveys have been commenced to extend the Otter Lake Branch of the Flint & Pere Marquette Railroad, Michigan, to Lexington, on the shore of Lake Huron.

It is proposed to build a narrow-gauge road from Dunleith, Ill., northward to La Crosse, Wis., about 150 miles, on the eastern or Wisconsin side of the Mississippi.

The Henderson & Overton R. R., from Henderson, Tex., northwest to Overton, on the International & Great Northern, is progressing, forty hands being engaged in track-laying.

Great activity prevails on the Wheeling & Lake Erie R. R., on Short creek and Piracy fork, where heavy cuts and tunnels are necessary. At Pine Hill work has commenced on a tunnel which is to be 550 feet long.

Preparations are making to extend the Chippewa Falls & Western road northeastward into Taylor county where it will connect with the Wisconsin Central road. Surveying is to commence immediately.

Track-laying on the Houston & Texas Central R. R. is now actively in progress on the extension of the Waco branch, from Waco northward. The first section of 10 miles, will, it is expected, be finished in February.

The Canada Southern railway had plans and estimates made for a tunnel through the limestone at their crossing at Grosse Isle. We have referred to that project more in detail in the NEWS, Vol. III, Nos. 20, 27, 30 and 53, where we also discussed the general subject.

State Railroad Commissioner Delano was in Chillicothe, Ohio, lately, inspecting the Valley railroad bridge at that point. The bridge shows no signs of weakness, but being a new structure it has been carefully watched. Some additional bracing has been ordered, so as to avoid all possibility of danger.

A company has been organized to build a branch railroad from the Jackson, Lansing & Saginaw R. R. to Alpena, Michigan, and a meeting of citizens of that city to favor the project has been held. The company want $50,000 from the city and a land grant from the State.

Brazil has now about twenty-five hundred miles of railroad in operation, of either the 5 ft. 3 in., or 39⅜ in. gauge, and the government is taking steps to increase the amount, having already decided to add some eleven hundred miles more.

The South Australian government proposes to spend $10,000,000 in constructing 400 miles of railway at once; New Zealand thinks of expending $6,250,000 for a similar purpose; and Tasmania and Victoria are also agitating the subject of railway grants.

The Canon City & Saguache R. R. Co. has been organized in Colorado to build a railroad from Canon City, the terminus of a branch of the Denver and Rio Grande, up the Arkansas, and through the valley of Pleasant Creek to Saguache, in the San Juan mining district. The capital stock is to be $1,000,000.

The permanent bridge of the Galveston, Harrisburg & San Antonio R. R. over the Guadaloupe is nearly finished, and it will be ready for use very soon. Track-laying is progressing steadily from the Cibolo towards San Antonio, and has nearly reached the Salado, where a bridge is being erected. This bridge may delay the track-layers for a few days.

Mr. C. F. Stephens, Chief Engineer of the Dallas & Wachita R. R., writes as follows under date of Jan. 24: "Track-laying is in progress. Five miles are down, and iron for 18 more is being rolled by the Kansas Mill Co. and shipped daily. Grading and bridging for 17 miles are down, the next six miles are under contract, exclusive of a bridge over Elm fork of Trinity river, and a party is in the field completing the location of the first 50 miles. The track is to be laid to Denton, the county seat of Denton county, and 40 miles from Dallas by July 1, and our charter compels 120 miles to be completed by Nov. 1. 1878. This will take us through the coal and copper fields, and open up the richest mineral country in the Southwest."

Now that public attention is so largely drawn to the subject of bridge building, by reason of the Ashtabula accident, it is not surprising that there is a continually increasing demand for such works as BOLLER'S IRON BRIDGES and "Greene's Graphical Analysis of Bridge Trusses." In both of these the information is conveyed in such plain terms that an intelligent idea of the different parts of the bridge, and the variety of trusses in most popular use is soon obtained, and the technical language which hitherto has conveyed rather indefinite ideas to the reader's mind is soon invested with new interest as each term is understood and the action of certain forces is perfectly comprehended.

NOTES.

The contract for timber for lock gates on the Lachine canal has been awarded to D. S. Booth, of Brockville, Ont. The amount of timber is nearly $200,000.

Mr. Glen affirms that iron can be profitably smelted at Whitby, Ont. The ore will come from Snowden, the limestone from Kingston, and the coal from Pennsylvania.

It is estimated that 10,000,000 acres of land in Algeria are covered with a spontaneous growth of the Alpha plant, the fibre of which is exported for the manufacture of paper work.

ONE great recommendation of BOLLER'S IRON BRIDGES is the popular style in which Part First is written—easy of comprehension to any man of average intelligence—while Part Second is "offered as an aid to Engineers not expert in this branch of the profession, and yet who are often called upon to act as inspectors."

During the past year th city of East Saginaw, Mich., has made extensive street and sewer improvements. There were 1,106 lineal feet of pavement—roadway 38 ft. wide—laid at a cost of $8,400, and 6⅓ miles of plank roadway, 8 ft. wide, at a cost of $6,475 for plank, and $1,019 for labor. The pavement consists of round yellow cedar blocks, cut eight inches in length, and laid on a foundation of sand four inches deep. The curbing consists of white oak four inches thick, and is laid generally in 16 feet lengths. The total length of public sewers in operation to date is about 5¾ miles of varying sizes, the largest being a brick sewer, 5 feet in diameter in the clear. Of private drains laid to sewers to date, there are about four miles.

AT a meeting of the special Committee on Water, of the New York Board of Aldermen, January 24, Gen. Viele stated that the present Croton aqueduct was in a dangerous condition and likely to burst at any moment. He also stated that additional storage reservoirs would give a sufficient supply of water, but would not increase the head. The only way to accomplish the latter result was to erect two or three force pumps in different parts of the city.

ARTIFICIAL DRAINAGE OF THE CALUMET MARSHES.*

Near large bodies of water there are often low lands, whose surface is either not high enough readily to shed rainfall, or so low as to be flooded by tides; these lands frequently become sufficiently valuable to attempt their redemption by artificial drainage. The first extensive system of artificial drainage was an attempt in 1634 to drain the low lands, some 400,000 acres in extent, adjacent to the river Ouse in England. The first attempt failed, but a second effort in 1649, reclaimed the lands, now known as the Bedford level.

Later, in 1839, the pumping engines at Harlem lake, in Holland, were erected to drain an area of 70 6-10ths square miles. These engines lifted 36 million tons of water per month, working from May, 1848, until July, 1852, to clear this area of water, averaging 12¾ feet in depth.

The pumping works at the Ferrara marshes in Italy, have been recently erected, draining the largest district ever concentrated in one system, which is 200 square miles in extent. These pumps are of the centrifugal pattern eight in number, capable of lifting 72,960 cubic feet of water per minute, or over 98 million tons per month.

Artificial drainage of such scope is unusual in the United Srates, and hitherto entirely unattempted in this vicinity. Measures are being taken, however, to drain a portion of the Calumet marshes, now known as South Chicago, situated within the corporate limits of the town of Hyde Park. This is the fruition of a scheme suggested twenty years ago by the late Stephen A. Douglas.

The plan described in this paper is not one for draining all the Calumet marsh, but the limits of the proposed drainage area include a small portion of that extensive territory of indistinguishable rivers, lakes and marsh which lies either side of the Illinois and Indiana boundary line. The ocean tides ebb and flow within fixed limits, seldom overpassed, but the surface of lake Michigan rises and falls in longer, irregular intervals, whose periods and amount cannot be foretold, but have been observed and registered. In 1847 the engineers of the Illinois & Michigan canal left a datum which was their estimate of extreme low water. The following statement shows the fluctuations of lake level since 1854, at which time the observations began:

Mean yearly elevation of surface of Lake Michigan, with reference to Chicago datnm, from 1854 to 1875 inclusive:

1854, 1.83; 1855, 1.56; 1856, 1.60;—1857, 2.42; 1858, 2.90; 1859, 2.98; 1860, 2.54; 1861 2,56; 1862, 2.50; 1863, 2,10;—1864. 1.57; 1865, 1.30; 1866, 1.07; 1867, 1.49; 1868, 1.01; 1869, 1.13; 1870, 2.09; 1871. 1.77; 1872, 0.81; 1873, 1.40; 1874, 1.67; 1875, 1.45;—for the first six months of 1876, 2.10.

In the past twelve years there has been a large amount of speculation and actual improvement in the vicinity of South Chicago; during this period the water in the lake has been at a low stage, averaging 1 28-100 ft. above datum. In 1876 the lake surface rose, and the ditches. previously adequate, no longer served to free the land from water. Their current, on the contrary, frequently set from the lake toward the interior of the country, and successive heavy rains accumulated water to a considerable depth over a thickly settled country. There was little trouble as long as the lake kept below a level of 1½ feet above datum, but a rise of over a foot—frequently augmented another foot, by northeast storms—placed a large territory below lake level.

The following is a brief abstract of the topography of the country: A large tract of low ground, varied at intervals by ridges, stretches from the lake westward, with slightly increasing elevation and rising in terraces, attains its maximum height of 90 feet in the Blue Island ridge. distant five miles from the lake. This ridge, two miles wide, and six miles long, an isolated mound of hard material, is cut off abruptly at its southern end by the Calumet creek, while its northern extremity gradually sinks to the plain.

Stony Island ridge, a rocky outcrop, rises abruptly above the marsh, within 1½ miles of the lake. The general trend is east and west, and by its connection at the western end with the high prairie, it divides the low ground lying north and south of it. For the present, only that portion of the low ground lying north of this ridge will be included in the drainage system, with the exception of a small tract lying southeast, on the opposite side of the Calumet river. South of Stony Island ridge is the large, shallow basin of the Calumet lake, bordered on all sides except the west, by a wide marsh, through which the Calumet river pursues a tortuous course.

The problem as presented to the engineer naturally assumes two divisions: First to keep out the waters of the lake; and second, to provide means of preventing the accumulation, and disposing of the rainfall. The problem of preventing inflow from the lake is almost entirely solved by natural defenses. A high, broad bank of sand follows the shore line, and various ridges stretching across the low lands only require to be connected by graded streets, a few feet high, to make the diking a complete protection on all sides. The sketch herewith presented may serve to indicate the topography of the area of low land into which the ridges stretch from various directions. The second division of the problem includes the greater range of calculation and forethought. There are two ways of providing for the rainfall, leaving the question of amount for future consideration. Reference to the map shows the high ground to have sufficient height to lead directly into the lake the rainfall which now flows to the low ground. To lessen the amount of water to be pumped, and to prevent floods over the low lands, it is necessary to devise a system of catch drains, which direct the water from the high ground into main ditches, leading over and across the low lands into lake Michigan, or emptying into lake Calumet.

By this system of catch drains, only the rain falling over the low ground would be pumped, and less powerful machinery and expense in maintenance would be needed. Tables of continued observation give annual, monthly, and daily rainfall. The maximum daily rainfall should determine the extreme ability of the pumping machinery. It is necessary to consider how much rainfall is evaporated, how much absorbed, or held suspended in the soil to find its way out by percolation, and, finally, what portion will be conveyed through ditches to the pumping station. The perfection of the system of ditches will regulate the rapidity of the accumulation of water. One inch rainfall in twenty-four hours is an amount ordinarily estimated, although this amount may fall in less than one hour. Supposing snow three feet in depth be followed by a warm rain, several days must elapse to melt this snow into its equivalent, three inches of water. The following table gives average annual rainfall in different parts of the United States:

Alabama and Louisiana	56"	Ohio	40"
Oregon	49"	New England	40"
Florida	48"	New York	37"
Virginia and Carolina	48"	Michigan and Wisconsin	32"
Tennessee and Kentucky	48"	Iowa and Kansas	31"
Georgia	44"	Texas	29"
Arkansas and Missouri	42"	California	18"
Maryland and Pennsylvania	41"	New Mexico	13"

*Paper read before the Civil Engineers' Club of the Northwest, Tuesday, February 6th, 1877, by Frederick Wilcox Clarke.

England has an average rainfall af 25", but the most startling instance is that in the vicinity of the Himalaya mountains, Asia, where 610", or over 50 feet of water falls in less than twelve months. For an accurate comprehension of the subject, it is requisite that the amounts of rain falling in different seasons should be carefully estimated. The average rainfall for this vicinity, taken from government observations since 1872, is 34 inches.

The rain of summer is greater than that of winter, including melted snow, being in the ratio of 3.55" average monthly rainfall to 1.93" for this locality, and is therefore nearly twice as much in the season when the ground is open to receive the rain and the warmth will soonest evaporate it. In calculating the amount of rainfall to be provided for within a given time, the retaining power of the ground must be estimated, as well as the maximum rainfall. A rainfall of one inch, spread over one day, amounts to 1,600 cubic feet per square mile per minute, not over one-quarter of which, it is expected, can be gathered at the pumping station. By referring to tables, including the last three years, the greatest daily rainfall will be found on Sept. 29 1875, amounting to nearly 3½"; the next, 2¼", occurred on July 27th, the same year. Both these rains fell in warm months and the water, percolating the soil, prepared by previous drainage, would reach the outlets gradually.

In the months when the ground is frozen the maximum rainfalls were 1 and 64-100 inches in March, and a day each in January and February of 1 ½ inches. It is reasonable to anticipate not over 2 inches in 24 hours during those months when the rainfalls of one day would reach the pumping station during the same interval. Two inches in 24 hours gives 3200 cubic feet per square mile, per minute. It is unfair, however to estimate that all the rainfall, of even the winter months will reach the pumping station; a large part will be held in hollows in the ground, and much contained in the ditches. Allowing 2 inches, as before stated, to fall in 24 hours, probably not more than one-fourth would reach the pumping station, and this would be distributed over at least two days.

Water which now accumulates in the limits of the low lands shown upon the topographical map, is largely rain which fell upon the higher prairie lands westward, outside the limits of Hyde Park. To divert this foreign water, if possible, is a point first to be considered. The low lands shown, have always been in the natural path of drainage for this outside area. As it may not be practicable to deny this foreign water a passage over Hyde Park, on its way to Lake Michigan, it is best to collect and transfer such water, by means of two main channels whose lines run directly eastward,using probably 79th and 87th streets for this purpose. These large drains are to have banks a few feet higher than the lowest ground through which they pass, keeping the water entirely within their channel, and all drains, connecting with the pumping station, are to be taken under them in culverts. While it is true, that perfecting the system of drains and ditches will more rapidly deliver rainfall to the pumps and tax their capacity, it is also true, that these drains and ditches will, in themselves, form a system of reservoirs in which the water can remain until pumped. This is entirely feasible as the low grounds are nearly level and the gradients of the ditches very slight. A large part of the land is subdivided into five acre blocks; supposing each block to be surrounded by a ditch, its length would be 1812 feet; allowing this ditch a width of 5 feet, and a depth of 2 feet, we have a reservoir capable of holding an inch rainfall over the entire five acres. Upon the basis of the foregoing calculations the Calumet pumping machinery was designed.

It consists of two centrifugal pumps whose respective capacity is 2200 and 4400 cubic feet of water, lifted 9 feet per minute. Having no large reservoir from which the pumps could draw a constant supply, it was deemed expedient to have a combination of pumping power that would be adapted to the varying amount of water accumulating at the pumping station. Each pump is driven by an upright non-condensing engine, adapted to work expansively and give a percentage of surplus power. The suction pipes of the pumps are 33 and 44 inches in diameter and their discharge pipes 24 and 32 inches diameter respectively. The suctions have an enlargement at the bottom provided with valves to retain the water when the pumps are stopped. The pumps draw water from separate chambers and gates, allowing either to be stopped and repaired while the other is working. The crank of the engines works off the end of the pump shaft. The engines are so designed as to give the requisite power with the number of revolutions required for the pumps. The boilers, three in number, are 4½ feet in diameter and 16 feet long; having thirty-nine 4-inch flues, and are connected above the domes by a steam drum. The engines and pump foundations are built in a caisson 30′ by 48′, sunk in an excavation to the blue clay, 14 feet below ordinary water. This caisson forms a pump well, guarded by two gates at the opening, for admission of water. Upon the walls of this caisson stands the enclosing brick building.

The main channel for the water will be crossed by a dam, opposite the pumping station, which serves to keep out the inflow from the Calumet river, and being provided with overflow gates gives egress to the water inside which might accumulate during severe or sudden freshets.

Estimating the drainage area at 20 square miles, the pumps have a capacity of 330 cubic feet per square mile per minute. The following comparison shows the pumping power provided in other instances. At the Ferrara marshes, Italy, the pumps dispose of 304 cubic feet of water per square mile per minute, or 1-125th of an inch rainfall per hour over the entire area, aggregating 69 inches rainfall per year.

The pumping works at Haarlem lakes, in Holland, pumped 425 cubic feet of water, per square mile per minute, or 1-88th inch rainfall per hour over the entire area, aggregating 98 inches total rainfall per year.

The processes of natural evaporation do not, to the ordinary observer, indicate any very great expenditure of force, yet, in reality the force equivalent of the rain supply over a hundred square miles alone for a single year is startling. It has been calculated that the amount of heat required to evaporate a quantity of water which would cover an area of 100 miles to the depth of an inch would equal the heat which would be produced by the combustion of half a million tons of coal. The amount of force of which this consumption of heat would be the equivalent corresponds to that which would be required to raise a weight of upwards of one thousand millions of tons to a height of one mile. But in comparing the natural means of evaporation and the mechanical means invented by man, the great advantage of the latter becomes at once apparent. Upon the basis of the foregoing calculation the coal consumed in evaporating an inch of rainfall over one square mile would amount to 5000 tons. Now an inch rainfall over one square mile amounts to 2,239,861 cubic feet or 140,000,000 pounds. If this be raised 6 feet it represents 840,000,000 foot-pounds. As many modern pumping engines show a duty of 60,000,000 foot-pounds for a hundred pounds of coal, the coal required to elevate an inch rainfall over one square mile would amount to less than three-fourths of a ton as against 5000 tons coal power exerted by the sun in evaporation.

There is no doubt that the future will see the problem of artificial drainage for these extended marshes solved on a grand scale in comparison with which the present scheme will seem an experiment, and that one of the numerous small lakes will be chosen as a receiving basin into which the entire district of about 40 miles will drain, thence being pumped into a channel leading into Lake Michigan.

ARCHES;

CONSIDERED GRAPHICALLY.

[Copyright 1877.]

(*Continued from page 30.*)

21. If the arched rib is fixed in direction at the ends (in place of being free to turn as previously supposed), by being firmly bolted to the abutments, or by having square ends, accurately bedded upon the skewbacks, a bending moment will generally exist at the points of support when the arch is loaded. By taking the piece of easily flexible wire before mentioned, clamping the ends firmly by two hand vises or otherwise, so as to fix the wire in the position of an arch, and then applying a load or the pressure of the finger, one can easily verify this statement for himself, and he will see that, for many positions of the load, the bending moment at one abutment is of the opposite kind to that at the other. The points at which the curve of equilibrium begins and ends will no longer be at A and B of Fig. 2, and some new conditions must be imposed, in order to determine these points.

22. Consider the effect of a single load upon the arched rib A C B of Fig. 4, which rib is fixed in direction at its ends. The curve of equilibrium will be two straight lines, and, as there may be bending at both points of support, it will be necessary to find the magnitudes of A I and B L, as well as of N G, three unknown quantities. Three conditions must therefore be satisfied.

Wm. Bell, C. E., in his paper "On the Stresses of Rigid Arches," etc., read before the Institution of Civil Engineers, of Great Britain, published in Vol. XXXIII of their transactions and reprinted in Van Nostrand's Engineering Magazine, Vol. VIII, March to May, 1873, and also Baker, in his book on "The Strengths of Beams, Columns and Arches," both writers treating the arch graphically, require but two conditions to be fulfilled for an arch with fixed ends. Such an assumption must be quite erroneous and must invalidate their results. Mr. Wilfred Airy, Associate of the Inst. of Civil Engineers, in his mathematical treatise on "Iron Arches," makes the same assumption in his analysis, which requires that the bending moment at the two abutments shall be the same. That this treatment cannot give correct results will be apparent, if we consider that a beam built in, or fixed, at its extremeties has different values for bending moments at the two ends, unless the load is symmetrical with regard to the middle of the span. If two conditions only are imposed, when three are necessary, many curves can be drawn, and the problem is left undetermined.

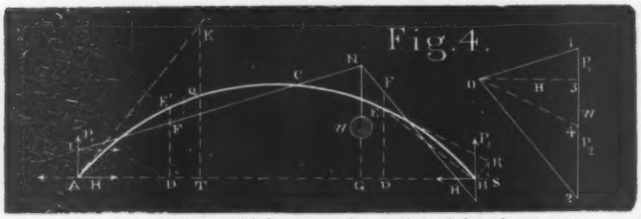


Fig. 4.

23. One condition which must be satisfied is plainly the one already used, § 11, that the change of span A B shall equal zero, or that

$$\Sigma E F . D E = 0 \qquad (4.)$$

Secondly:—As the *change of inclination* between any two contiguous points is directly proportional, in direction and magnitude, to the bending moment at that point (for the elongation and compression of the fibres on the two sides, upper and lower, of the rib result from this bending moment, and cause whatever change of direction or inclination the rib may take on at the point), and as the bending moment has been proved to be proportional simply to the ordinate E F, the increase of change of inclination at any point is proportional to the ordinate E F from that point of the rib to the curve of equilibrium.

The reader must distinguish between the change of inclination produced by flexure and the original inclination of the rib to the horizon at each point due to the curve to which it is constructed. If an arch is loaded it assumes a form slightly different from its shape when unloaded. The angle, at any particular point, between the two tangents to the curve of the rib, before and after it is loaded, is the *change of inclination* at that point.

Starting from A, the total change of inclination at C will be proportional to the sum of all the ordinates between A and C. On the other side of C, where the straight line crosses the rib, the bending moment being of the opposite kind, the changes of inclination will be in the opposite direction, and, in any summation of ordinates, for instance from A to E, must be subtracted. Then, as the end B is also fixed in its original direction, if we sum up all of the ordinates E F, from A to B, this sum must be zero. Therefore the second condition to be realized is that

$$\Sigma E F = 0, \qquad (6.)$$

or that *the sum of all the ordinates between the arch and the curve of equilibrium on the inside of the arch must equal the similar sum on the outside.*

24. Thirdly and finally:—It will be seen by Fig. 4, that, since the displacement B R of B, relatively to the point E, in case B could move, has been shown, by § 10, to be proportional to H. E F. E B, the vertical component of this displacement may, by a similar proportion to the one used in that section, be put as

$$S R = B R . \frac{D B}{E B};$$

therefore S R varies as $\frac{E B . H . E F . D B}{E B}$, or as H . E F. D B.

If the products E F. D B should be summed up for all points from A to Q, for example, we should get a quantity proportional to the vertical displacement of Q arising from the separate minute displacements between A and Q. If we pass beyond C, we have products with an opposite sign, and it then appears that, since the ends at A and B are fixed both in position and in direction, the sum of all the products between A and B must equal zero, or, since H cannot equal zero,

$$\Sigma E F . D B = 0. \qquad (7.)$$

Therefore the third and last condition is that *the sum of the products of each ordinate between the arch and the curve of equilibrium by its distance horizontally from one springing point must equal zero.* It is immaterial which springing is chosen, but all the D B's must be measured to the same abutment.

25. It will perhaps be expedient to dwell upon this equation a little longer, for the question will apparently arise why this condition is not also properly applicable to an arch which is jointed or hinged at the ends. Let a tangent A K be drawn to the rib at the point A, and a vertical line be dropped from it to the point Q. If the arch is now bent at the point E′, by a bending moment which is proportional to E′F, the point Q is moved a distance proportional to E′F multiplied by the distance from E′ to Q; but the distance which Q moves in the line Q K will be proportional to E′F multiplied by the horizontal projection of E′Q or D T, and similarly for moments at all other points between A and Q. As the tangent at A is fixed in direction in this case, the movement of Q away from the extremity of K Q, or its movement in relation to the tangent will be proportional to the summation of the E F's multiplied by the D T's; and therefore the distance of B from a tangent at A must be unchanged by any load, or its displacement must be zero, as above. In the case of the rib hinged at the ends the tangent at A changes in direction, and this condition cannot be applied. If, however, we should have an arch which was fixed at A and hinged at B, this condition would be necessary, and all the distances D B would be measured to the hinged end, while the second condition would not apply, and would not be needed.

This third condition was first applied to the determination of the bending moments in continuous bridges and pivot draw spans in "Graphical Analysis of Bridge Trusses,"* and so far as we are aware, is to be found nowhere else.

26. It will be seen that the arch of Fig. 4 is cut by the curve of equilibrium in three places, and it may be cut at four points, giving as many places of contraflexure. The areas on opposite sides of the rib represent bending moments of opposite kinds, and of which kind is readily known, if one remembers that the arch always moves from the curve of equilibrium. The amount of the weight, not being contained in any of the equations of condition, does not affect the position of the curve; for H is constant for all points of the arch for any given load, and, not being equal to zero, is thrown out of the equations. But the weight W does affect the value of H.

27. If 1-2 represents W, in the stress diagram of Fig. 4, and 1-0 and 2-0 are drawn parallel to N I and N L, 0-3, drawn horizontally, will determine the horizontal thrust H, while the load line will be divided at 3 into the two vertical components, P_1 and P_2, of the reactions, as marked. These vertical forces are not the same as would be obtained for the case previously considered, nor for a beam only supported at the ends. If we notice the arrows drawn at the abutment A, we see that, supposing P_1 were at first the fraction of W due to its position over G, or $\frac{G B}{A B}$ W, we have also at A, besides the horizontal thrust H, a couple H. A I. There is another couple at the other abutment, which may be of the same or opposite kinds; their algebraic sum can only be balanced by vertical forces at the two abutments acting with a lever arm of the span, and these vertical forces must either be taken from or added to the first supposed P_1 and P_2, bringing them to the amounts found by the stress diagram. The supposed supporting forces would be equal to the division of 1-2 made by a line drawn through 0, parallel to a line from I to L. The effect of the couple is the same as if P_1 had been calculated for the point where N I would meet the horizontal line.

The remarks on shear in § 20 apply equally well here. The direct compression in the rib at any point is obtained, as before, by drawing a line through 0 parallel to the tangent to the rib at the point in question. Thus the compression at E is 0-4.

*"Graphical Method for the Analysis of Bridge Trusses, extended to Continuous Girders and Draw Spans: Greene"; New York. D. Van Nostrand, Publisher. 1875.

(*To be continued.*)

OBSERVATIONS ON AMERICAN AND FOREIGN RAILWAYS.

In the year 1874, the government of Victoria sent Thos. Higinbotham, M. Inst. C. E., Engineer-in-chief of the Victoria Railways, on a tour of inspection of the public works of that class in the United States, Europe and India, so as to obtain for Australia the benefit of such knowledge as Mr. Higinbotham might thus acquire. He occupied the greater part of two years in the trip, and has embodied its results in a large octavo pamphlet of 72 pages, entitled "*Report of Observations on Railways made during a Tour in 1874 and 1875, undertaken by Direction of the Government of Victoria.*" We are indebted to Mr. E. S. Chesbrough, City Engineer of Chicago, for the opportunity of reading a copy sent him by Mr. Higinbotham, and from it we make some abstracts which may be of interest to our readers:

Mr. Higinbotham left Melbourne for San Francisco on March 10, 1874, arriving April 14. He then passed over the Central Pacific Railroad, of which he observes:

"In the construction of this railroad there are, as might be expected, many marks of great haste observable; and very inferior and perishable materials have in numerous instances been used. It would be a great mistake, however, to suppose that American Engineers of good professional position defend such construction on any other ground than that of necessity. The grand object both on this and the Union Pacific Railroad was to get the track laid as quickly as possible; and, in the case of such enormous distances as these lines cover, it was necessary, in order to do this, to make use of any material which was at hand." "I rode on an engine for some hours when crossing the Sierra Nevada; there were three engines attached to the train; the road was rough, and the speed at times on falling gradients very great, but the drivers appeared to have perfect confidence in their engines that they would not leave the road. I had opportunities of speaking to several drivers, Englishmen, who had driven in England; they all preferred the American to the English engine, which they said could not keep on such roads as are commonly to be found in the Western States."

Similar testimony was given later, from the experience of the Grand Trunk Railway, with both kinds of engine.

He then examined the Denver and Rio Grande lines, 3 feet gauge, at that time open for 120 miles. The maximum grade is 75 ft. per mile; it has one short curve of 478 feet radius, but generally the curves are not unfavorable. The rails are 30 lbs. to the yard, sleepers 6 ft. 6 in. long, 8x8 in section and spaced about 2 ft. 6 in. between centers; cuts 12 ft. 6 in. wide, embankments just wide enough to carry the sleepers, no ballast, no fences, bridges and culverts of timber; original cost $14 000 per mile, but much additional money was being expended on it; all surplus from earnings going towards improving the lines. The rails are too tight and are wearing out fast. The rolling stock is proportioned as follows:

Passenger engines, cylinders, 9"x16"; drivers, two pairs coupled, 36" to 40"; wheels of truck, 24"; total wheel base, 11' 11"; rigid base, 6' 3". Weight, 25,000 lbs., on drivers, 20,000 lbs. Freight engines, cylinders, 11"x17"; drivers, three pairs coupled, 36". Weight 35,000 lbs., on drivers 31,000 lbs. Passenger cars, 40 ft.x 7' 9" outside. Weight 12,000 lbs., to carry 33 passengers. Freight cars, box, 24 ft. long, weight 8 000 lbs., to carry stores; coal cars 24 ft., weight 7,500 lbs., to carry 8 to 9 tons; flat cars, 24 ft., weight, 6,000 lbs., to carry 8 to 9 tons.

It is admitted that the line could be worked with much greater economy, if more powerful engines could be used on it; but this would be impossible without heavier rails.

The Colorado Central, Kansas Pacific, and Missouri Pacific were passed over; but he made no special comments. The Chicago, Burlington & Quincy R. R. permanent way is spoken of as a marked improvement on the lines in the West over which he travelled. He quotes at considerable length from a report of the joint Commission of Railroad and Harbor Commissioners, made at Boston in 1871, on "Terminal Accommodation for Passengers," in which they proposed that four separate passenger stations, each 700 ft. long by 125 ft. wide, with streets between and adjoining them not less than 60 ft. each in width, should be provided for the passenger traffic which centers in Boston, the population of which, in 1874, was about 325,000. The daily passengers were about 58,000.

He travelled from Chicago to New York by the Michigan Central, Great Western and Erie Railroads. He remarks on the pattern of rail; the use of spikes in place of screw bolts to fasten the rail to the sleeper; the direct support of the fished joint, in place of its being suspended between two sleepers; the iron bridges, the station buildings, etc. "The permanent way of the best of the railroads of the Eastern States is not, in my opinion, equal to that of the best lines in England; the road bed is not so good, nor the drainage so complete, and dog spikes do not make so good a fastening as screw bolts." But he remarks that screw bolts cannot be used wh re a road bed is frozen hard in winter. He next went over the New York Central & Hudson River R. R., the Ottawa & Prescott and the Grand Trunk railways. He inspected the Toronto and Nipissing. 88 miles, and the Toronto, Gray & Bruce, 190 miles, both railroads of 3 ft, 6 in. gauge, and often quoted in narrow gauge discussions, What he states in reference to these lines will probably be of interest. As they are alike he describes only the former:

"It is a well constructed line of its kind, has a good road bed of gravel ballast, and iron rails, Vignole's pattern, weighing 40 lbs. to the yard, laid on transverse sleepers. There are no works of any importance, the line being kept on the surface of the country. The ruling gradient is 105 feet per mile, and the greatest length of this gradient is 4,650 feet. There is one short curve of 400 ft. radius, but the ruling curve is 600 ft. radius; even this is complained of as causing serious additional expense in working the line, more especially when it occurs on a steep gradient. The station buildings are very small and incomplete. Engine drivers are ordered not to run over any mile of the line with a passenger train at a higher speed than twenty miles an hour, or with a freight train than twelve miles an hour. This railroad has cost $18,000 per mile, including land, stations, rolling-stock and engineering. Grain, lumber and firewood are the principal items of freight, and in the year endfng June 30, 1873, 82,000 passengers had been carried. In the same year the gross receipts had amounted to between £8 and £9 per mile per week, and the working expenses were about 56 per cent. of the gross receipts. The traffic was improving. It was admitted to me by all those connected with the management and working of the narrow gauge railroads in Canada that a false economy was adopted in constructing them, and this admission was made by gentlemen who had been the most earnest advocates for a gauge of 3 ft. 6 inches, for steep gradients and numerous and sharp curves wherever expense could be saved by using them, and also for light rails, engines and rolling-stock. The experience of a year and a half's work of the line had completely changed their opinions. The 40 lbs. iron rails, with which the lines were laid, were wearing out, and steel rails of 56 lbs. to the yard were used to replace them; the light engines could not haul profitable loads, and the sharp curves greatly reduced their efficiency. I was told that it would have paid well to have spent more money on earthworks, and by so doing avoided the sharp curves and shortened the line; and that it was bad economy to use any curve of less radius than 1.000 feet, even with a gauge of 3 ft. 6 inches. As to this gauge there was also a complete change of opinion. The saving which had been effected by using it had not been found to compensate for the evils of the break of gauge with the Grand Trunk railway of Canada. I was assured there was every probability that both lines would be altered to the gauge of the Grand Trunk, which is now 4 ft. 8½ inches; and the Victoria R. R., a new line in connection with the Toronto & Nipissing line, the works of which had just been commenced at the time I was at Toronto, was to be made of this gauge. It appeared to be a settled opinion in Canada that no more railroads of the 3 ft. 6 inches gauge would be made there; not because lines on this gauge could not, with suitable rails and engines, carry the traffic of the districts through which they pass, but because the expense and other evils of a break of gauge more than outweighed any economy which could be effected by using the narrow gauge."

The English rolling-stock had proved a complete failure and has been replaced by American engines and cars. One Fairlie engine on the Nipissing road was well spoken of, as also this class of engine on the Denver & Rio Grande road: "with these two exceptions, the opinions which I heard from those who had experience of the Fairlie engine were most unfavorable." The passenger engines were, weight 33,600 lbs., cylinders 11" 18", 4 driving wheels, 39" diameter. Freight engines 56,000 lbs., cylinders 14x20, 6 drivers, 39" diameter. Passenger cars, 40 ft.x8' 8", outside, to carry 40 passengers. and weighing 26,400 lbs. Box cars, 28'x8', weight, 14,500 lbs., to carry 10 tons.

Of the break of gauge between the Grand Trunk and the U. S. railroads, he says:

"All the numerous plans far transferring freight from the cars of one gauge to those of the other had been tried, and also instructions for lifting the bodies of the cars off the bogie trucks and transferring them with their freight; but these various schemes were found to be mitigations only of a great evil, and, as I have already said, it was determined to alter the gauge from 3 ft. 6 in. to 4 ft. 8½ in."

The new steel rails of the Grand Trunk weigh 65 lbs. per yard. Cast-iron wheels are not liked on that road.

Mr. Higinbotham inspected the Mt. Washington railroad, the steepest in the world, and the pioneer of mountain lines; length of line 3 miles, average rate of ascent 1 in 4, steepest gradient 1,980 ft. in a mile, or 13½ inches in 3 feet., line worked by rack on track and pinion on engine, time of ascent 1½ hours. He then passed over the Boston, Concord & Montreal railroad, and from Boston to New York by the way of Springfield. "On some lines the rolling-stock is heavier than on others, and for several years there has been a constant tendency to increase the weight of the stock. This tendency seems now to have reached its limits, and there appears to be a stong feeling on the part of railway companies that the dead weight carried is excessive." He draws a general conclusion, from weights on various roads, that an ordinary passenger car in the United States weighs 630 lbs. for every passenger which it can seat; that a box freight car, covered, when fully loaded, carries 1 1-7 times its own weight; and that a flat or platform car carries 1 2-5 times its own weight. He praises the railroad stations of the Eastern States; the yard room is considered ample, the "Train Dispatcher" is spoken of, etc.

What he thinks of our bridges is noticeable, as coming from an English engineer:

"The iron bridges in the United States are among the most remarkable of its engineering works, and they differ in many respects from English bridges. In the former much greater care is taken in the selection of the iron than in the latter, and they are therefore lighter; pin connections are used invariably instead of rivets for all main parts, and all the fittings are engine-turned and planed. A greater depth of girder in proportion to the span is used in the States than in England; a depth of one-ninth to one-twelfth of the span is common in England, and one-fifth in the States. The bridge work is completely fitted before leaving the shops where it is made, and can therefore be erected with great rapidity and with unskilled labor; and being divided into a number of parts, is easily and economically transported. The differences in the two systems have arisen, no doubt, to a very great extent from the different conditions under which bridges are built in the two countries. In the United States very much larger spans are required as a rule than in England; the quality of the iron is superior to that in England, and economy in transport when distances are so vast, is of great importance. There can be no doubt that American engineers adapt their bridge designs to the conditions with which they have to deal with admirable skill; but it is questionable if these designs would be suitable either in England or here, where the conditions under which bridges are built are so different from those in the States."

Mr. Higinbotham spent five months in the United States and devotes 30 pages out of 72 to this country

He next sailed for England where he arrived in September, 1874, went to Glasgow and thence to Ireland. He states that in Ireland the bridge rail on transverse sleepers is condemned and going out of use on account of the difficulty of getting good joints with it, and that steel rails of from 73 lbs. to 80 lbs. per yard are going down in its place. The traffic on the Irish railways is small. The Great Western Railway and lines in connection with it, in the southwest of England and in South Wales were originally laid to the gauge of 7 feet. Most of the line has now been altered to 4 ft. 8½ in. The standard rail of the Great Western Railway is double-headed and reversible; it weighs 80 lbs. per yard, and is laid in chairs weighing 35 lbs. each, fastened by two ¾ inch bolts, passing through a cast-iron washer, and secured by a wrought-iron nut. The sleepers for the 4 ft. 8½ in. gauge are of Baltic timber, creosoted, and measure 9 ft. by 10 in. by 5 in. The intermediate sleepers are 3 ft. from center to center, and at the joints 2 ft. Express trains on the 7 ft. gauge are run at an average speed of 35 to 40 miles per hour by engines with a single pair of 8 ft. drivers. The narrow-gauge express engines have 7 ft. drivers. The engines have inside cylinders, wrought-iron crank axles, copper fireboxes, wrought-iron tubes, boiler plates ⅝" thick, pressure 130 lbs. per sq. inch. A disc wheel, with steel tire, cast-iron boss and remainder of teak wood, is coming into general use on this line.

The Westinghouse brake and the Smith vacuum brake are next discussed. Then follows a few facts in regard to the Metropolitan Underground railway in London, At the locomotive shops of the London and Northern

railway Bessemer steel is largely used for frames, boilers, fire-boxes, crank-axles and wheel ties. In coming to England from the States one is struck with the want of uniformity in the class of locomotive which is employed to do a particular work. One road runs an express locomotive with a single pair of drivers 8 ft. 1 in. diameter, while a lighter line uses express engines with two pairs of coupled drivers 6 ft. 6 in. diameter, and many engines on fast trains have only 5 ft. 6 in. drivers. American engineers condemn large driving-wheels, because they cannot be properly balanced, and experience has proved that the highest speed which is practicable can be obtained with wheels of moderate size. Inside cylinders are the rule in England. There has been a marked improvement in English rolling stock; the carriages are loftier and generally more roomy and comfortable than they used to be, and the wagons are built to carry greater loads. The statistics of passenger traffic in the United Kingdom for five years, ending with 1874, shows that in every 1,000 passengers, 90 travel by the first-class, 183 by the second-class, and 727 by the third-class carriages. Applying these figures to the average weight of each class of carriage, the result shows that the average dead weight per seat in the railway carriages in the United Kingdom is not quite 450 lbs. The block system with the interlocking of points and signals is very highly spoken of.

Mr. Higinbothom next goes to France, notices two-storied railway carriages on a line around Paris, and comments on the construction of other carriages and wagons. The coupling of the carriages are similar to those in England, but goods wagons are all furnished with screw couplings; and safety chairs, which have been discarded in England, are in use in France. French engines have a very heavy and clumsy appearance compared with those of either England or America. In many of them the eccentrics are outside the wheels; but this practice is being abandoned. Some of the passenger carriages are on six wheels and some on four; four-wheeled carriages form the great majority. There are about 19,000 kilometres (11,875 miles) of railway in France. Of these about 5,000 kilometres return a profit, some of them very large; but, of the remaining line, some do not ever pay working expenses.

He next passes over the Paris, Lyons and Mediterranean Railway from Paris to Nice, and then to Venice, visiting the Mont Cenis tunnel on the way. In construction the railways in the north of Italy follow the French railways, but the quality of the work is not so good, the lines are not well maintained, and the condition of the rolling stock is also very inferior to that on the great French lines. From Venice he went to Trieste and thence by railway over the Semmering Alp to Vienna. The tunnels and lofty viaducts at this pass are of much note. The carriages on the Austrian railways had wrought-iron sides, with very strong wood framing. Sheet iron is used for panels. Steel fire-boxes and boilers have been tried on the State railways, but the experiment on the whole was not successful, though at first promising. Corrugated copper fire-boxes are now being tried. The inferior quality of the fuel in Austria is a serious difficulty to engineers. One pound of the best Austrian coal will not evaporate more than 6 pounds of water, and the same weight of inferior coal will not evaporate more than 3 pounds. This makes very large fire-boxes and long boilers necessary. The engine drivers all work on premiums for economy in the consumption of fuel.

The rolling stock in North Germany, speaking generally, is of very strong construction, and the useful load bears a good proportion to the gross load. The more recent vehicles have frames of wrought-iron, and steel disc wheels are very generally used.

The narrow gauge railways of Norway, constructed by Mr. Carl Phil, were visited. At that time, 194 miles of railway, on the 3 ft. 6 in. gauge were in operation, about the same length was in course of construction, and 170 miles were projected. The cost per mile varied from £2600 to £6900. These lines, having almost exclusive possession, are not troubled by break of gauge.

"The Norwegian narrow gauge railways are well-constructed lines of their class, and appear to be sufficient for the light traffic of the country. The ordinary formation width is about 13 feet. The ballast is good and sufficient in quantity. The lines are fenced throughout, and there are gates at all road crossings. The culverts are built of stone; the bridges of large span are of stone and iron, but the small spans are of wood, and these constitute the great majority."

"The rails are laid on transverse half-round sleepers 6′ 6″ long, by 9″ by 4½″; the Vignoles pattern of rail is used; the 40 lbs. rail has a base of 3¼″ and a depth of 3 and 9-16ths″; the joints are fished, and are suspended between two sleepers."

The sleepers are spaced 2′ 9″ at middle of rails, changing gradually to 18″ at the joints. The rails are fastened by 5″ spikes, two to a sleeper.

There is very little of general interest in regard to railways in other countries in Europe. The average fares for passengers by first, second and third-class carriages on continental railways is put at about 1.8 *d.*, 1.2 *d.*, and 0.6 *d.* respectively per English mile.

He went to Bombay in October, and, as the Indian railways were constructed by English engineers, he did not expect to meet with any novelties. The introduction of the gauge of one metre in some parts of India had brought about some of the troubles experienced elsewhere.

"The adoption of so wide a gauge as 5 ft. 6 inches for the lines of railway which were first made in India was certainly unfortunate. If the 4 ft. 8½ in. gauge had been used, the metre gauge would probably never have been introduced. The earlier lines, having been made under the extravagant system of a guarantee by the Government of five per cent. on the amount which the companies expended, were, as might have been expected, very costly. This high cost was attributed to the gauge, hence the introduction of the narrow gauge. The great Indian Peninsula Railway passes over the mountains by the employment of changing stations and zig-zags. Iron pot sleepers are largely used, both with broken stone ballast and sand and gravel. The road laid on these sleepers does not run so smoothly as on wood. The first cost is greater than for wood, but they are more economical in the end, as the latter are destroyed by white ants; these do not work in the sleepers in the road, as the passage of trains disturbs them, but they quickly destroy sleepers which are in stacks. The wooden keys for fastening the rails to the chairs were destroyed in the same way, so that steel keys are now employed. The heaviest gradient in crossing the Ghauts is 1 in 37 and 1 in 40 is common. The engines on these inclines are of the tank class with four pairs of coupled wheels, 4 ft. diameter; they weigh 50 tons in running order. Catch sidings are employed, having a gradient of 1 in 10 opposed to the gradient of the main line, to check any train which may run away. All trains descending have to pull up at the points of each catch siding. The greatest works on Indian railways are the bridges over rivers. They are almost all iron girder bridges of large spans. Many of the rivers are subject to violent floods, and scarcely a year passes in which they do not produce disastrous effects on the railway works. The bridge piers are, many of them, stone or brick. Some difficult foundations were made by means of brick wells; in the Chenaub bridge these have been carried to a depth of 60 feet below the bed of the river.

CHIEF JUSTICE CURTIS, of the Supreme Court, New York city, has decided in favor of the right of the N. Y. Elevated R. R. Co. to construct their road across the Battery.

A GENERAL (Quarterly) meeting of the *American Institute of Mining Engineers* will be held in New York, beginning Tuesday, Feb. 27th, at 8 P. M., at No. 4 East 23d street.

A BILL has been introduced in the New York Legislature, now in session at Albany, for the appointment of a "Sanitary Inspector of Schools," whose duty it shall be to protect the children attending the public schools from the evils arising from bad sewerage and insufficient ventilation.

AT the meeting of the Franklin Institute, Jan. 17th the following officers were elected: —

President, Robert E. Rogers, M. D.; Vice President, Henry G. Morris; Secretary, J. B. Knight; Treasurer, Fred. Fraley. Managers to serve three years,—Prof. E. J. Houston, Enoch Lewis, C. H. Banes, Wm. Helme, Sam'l Sartain, Chas. Bullock, John Sartain, C. Chabot. Auditor, Wm. Biddle. Representative to the Pennsylvania Museum and School of Industrial Art, J. B. Knight.

AT the last meeting of the Civil Engineers' Club of the Northwest, Mr. W. B. Rice exhibited an improved style of pontoon bridge, the model of which was examined with a great deal of interest and attention by the members of the Club. The patentee was called upon by Messrs. Hjortsberg, Chesbrough, Morehouse, Smith, Greeley, Thomes, and others, to explain in detail the various parts and workings, and favorable opinions were expressed. The principal feature of Mr. Rice's improvement consists in overcoming the varying grades of the approaches by keeping the track level automatically at all stages of the water. We hope to be able to give a more extended notice of this important improvement in bridge construction at an early date.

THE following are elections and changes and corrections of members of the American Society of Civil Engineers for January:

Additions.—James G. Batterson, [F.] Hartford, Conn., June 7, 1876; George H. Mendell, Maj. of Engs., U. S. A., Sept. 6, 1876. *Changes and Corrections.*—Arthur Beckwith, Room 54, Coal and Iron Exchange, Cortlandt and Church streets, New York; Leonard F. Beckwith, President Fire Proof Building Co. of New York, Room 54, Coal and Iron Exchange, Cortlandt and Church streets, New York; Charles E. Billin, Box 2580, Philadelphia, Pa.; L. G. F. Bouscaren, Cons. Eng. Cincinnati Southern R. R., Cincinnati, O.; Thos. B. Brooks, Monroe, N. Y.; Elmer L. Corthell, South Pass Jetty Co., 122 Common street, New Orleans, La.; Charles G. Darrach, 3906 Woodlawn street, W. Philadelphia, Pa.; Edwin A. Doane, Myrth Block, East Fifth and Utica streets, Oswego, N. Y.; Arthur L. Ford, 80 West Sixth street, Oswego, N. Y.; James C. Kennedy, Care William Kennedy & Sons, Owen Sound, Ontario, Canada; Peter A. Peterson, Chief Engineer Q. M. O. & O. R. R., Montreal, Canada; Andrew J. Post, 136 Magnolia avenue, Jersey City Heights, N. J.; Thomas S. Sedgwick, 732 Twenty-first street, N. W. Washington, D. C.; Robert P. Staats, 349 West Fourteenth street, New York.

FROM the recent report of the test of the West Side Pumping Works, in this city, we gather that the two engines, coupled, pumped during the whole test at a rate somewhat in excess of thirty millions gallons in twenty-four hours; that they delivered the water under a head equivalent to elevating it over 155 feet above the surface of the water in the pump well; but that the engines did not develop a duty of 90 millions pounds of water lifted one foot for each 100 lbs. of coal consumed. In the first two points the engines fulfilled the contract but in the last one they failed. The commissioners are of the opinion, however, that under more favorable circumstances of operation and weather, and with more skillful firing, a higher duty can be obtained. The experts who conducted the test were Moses Lane, Chas. H. Haswell, Chas. Hermany, Thos. J. Whitman, and Henry Warrington.

The question then arises whether the city shall take the engines. As they have failed to satisfy the requirements of the contract in the duty test, the contractors may be required to make that specification good, for which they have some nine months' time, or to take the pumps away. In the latter case the city will be unable to supply their place for a considerable time, and the West Side works are needed forthwith, not only to fully supply that portion of the city, but to relieve the present works on the Lake Shore from the constant strong draught on their energies.

THE advocates of underground railways in the city of New York are pushing forward with renewed vigor, and it begins to look as if something would soon be done. That the work has not been inaugurated before, and even carried nearly through to completion, was due to the number of schemes which were urged at the same time. Very little of the talk and few of the applications for charters from the Legislature were sincere. There was much speculation mixed up in the matter, a desire to head off rival projects, and a strong opposition started and encouraged by the proprietors of present modes of conveyance. Then property owners were sensitive, and afraid of damage to their estates. The Gilbert Elevated Railway is the only one which has pushed ahead in spite of hard times and litigation, so that now it is acknowledged by disinterested persons to be a safe, comfortable, quick and altogether satisfactory line of communication between the two ends of its route. More improvements, additional rolling stock and an extension of the line are now assured.

Besides this line there have been advocated, an ele-

vated line running over the middle of an avenue; an underground one in a subway in the same location; an elevated road through the middle of the blocks; and an underground line in a single tunnel. The subway was to extend from curb to curb, or house to house, and give an underground, a two-storied street, one for rapid transit and freighting business, the other for ordinary business and pleasure uses.

SINCE the New York & Harlem Railroad has completed its new sunken tracks from the extreme northern boundary of the city, through Fourth avenue to Thirty-second street, a distance of about twelve miles, it is now urged that the construction of an underground road of about two and one-half miles, from the Grand Central depot to the City Hall, would put the upper and lower parts of the city in communication with one another by steam. Such a line seems entirely feasible, and it could be built in a very short time. The New York & Harlem road, paying prices for material and labor that ruled at the time of letting their contracts in 1872, constructed a roadway for four tracks, through more than half the length and the rockiest part of the city, for some $1,500,000 per mile. The two central tracks are divided from the other ones by heavy walls, and the middle portion is generally uncovered, while the side tracks are covered by iron beams and girders with brick arches, the whole forming the roadway for Fourth avenue. Considering the cost of this mode of building, the width required for the road from the depot to the City Hall, the fact that a simple tunnel would be excavated, and that there would not be so much rock cutting, the estimated cost for the extension is put at $1,000,000 per mile. Mr. Wilson, of the firm of Fowler & Wilson, engineers of the London Underground railway, has carefully examined the ground, and has placed the cost, excluding stations, and at present prices, at less than the above sum. It is desired to raise $1.000,000 among capitalists in New York, and to get the balance from other sources. If the enterprise is properly administered, there is no doubt but what it will pay handsomely.

THE most prominent man now before the public in connection with the proposed Detroit Tunnel is Wm. Sooy Smith, C. E., who offers to provide the money and build the tunnel if he is guaranteed the interest on the money expended, and when the success of the scheme is demonstrated he is to receive his pay.

Mr. Jas. F. Joy, the well-known railway magnate, having denounced the proposition of Mr. Smith as the scheme of a visionary enthusiast, without taking the trouble to examine into the merits of the proposed plan, we have been led to make some inquiries as to the record of the engineer whose reputation is thus rudely assailed, and we have learned the following facts:

W. Sooy Smith graduated from the Ohio University in 1849, and from West Point Military Academy in 1853, taking the degree of M. A. from the Ohio University in 1860. In 1854 he commenced his practice in civil engineering as Chief Asst. to Col. J. D. Graham, U. S. Eng. in charge of the harbor improvements on the Upper lakes. He was engaged in the surveys for the location of the International bridge at Buffalo, and in surveys for a ship canal around Niagara Falls on the American side. He removed the submerged rocks from Buffalo Harbor by blasting without drilling. He was subsequently Chief Engineer for a New Jersey Iron Bridge Building Co. by whom he was sent to the West Indies in charge of some bridges to be erected there. At the time the war broke out he was engaged in putting in pneumatic cylinders for the piers of a bridge over the Savannah river; but entering the army he served until near the close of the war when he was obliged to retire on account of ill health. After the close of the war he was employed by the U. S. Lighthouse Board on the repairs of the Waugashanse Lighthouse, which stands on a rocky shoal 2½ miles from shore. While engaged on this work he designed and sunk the first pneumatic caisson put down in this or any other country, with which he surrounded the lighthouse tower and carried to satisfactory completion the work on which he was engaged.

As Chief Engineer of the bridge-building firm of L. B. Boomer & Co., now the well-known American Bridge Co., he superintended the construction of the first pneumatic cylinders sunk west of the Alleghanies, at Omaha and Leavenworth, for the bridges over the Missouri river at these points. He was also the first engineer to introduce the use of the screw pile in the west, which he did in sinking the piers of two bridges in Nebraska, following it with putting in screw pile foundations for the piers of a bridge over the Mobile river, 14 miles from the city of Mobile.

From first to last he was the engineer of the great railway bridge over the Missouri river at Booneville. Besides these important works he has from time to time been engaged on various public works of more or less importance. He has also served on several important engineering commissions, and he originated the effort to induce the U. S. government to appoint a commission to establish and carry out a series of tests of iron and steel, of which commission he is a member.

He was the chairman of the Centennial Commission of the American Society of Civil Engineers on Foundations and Masonry, and was one of the experts appointed by the government to examine the foundations of the Chicago Custom House, and is now one of the board to devise means for the drainage of South Chicago.

In view of the fact that he has had a very extensive experience in under-water engineering and in the development of the pneumatic system, assisting in the preparation of plans for some of the most difficult under-water works in the United States, such as tunnels, caissons, pier foundations, etc., it is but fair to presume that he knows whereof he speaks when he makes his proposition respecting the Detroit Tunnel, and if his scheme is a visionary one, it must have a pretty fair showing for success to induce the capitalists who are backing the engineer to squander their money in the project.

Personally, Mr. Smith is a most matter of fact individual, and if the quite ample fortune which he has amassed from his profession is a sign of his "visionary" prochivities' a few of his brother engineers will pray to to be blessed with the same failing, Mr. Joy notwithstanding.

PROPOSED SCIENTIFIC EXPEDITION AROUND THE WORLD.

The object of the Expedition is to visit points of general and special interest; to obtain knowledge of the manners and customs of different races, and to study Architecture, Archæology, Geology, and the Fauna and the Flora of new or little known localities, and to make collections and studies in natural history generally.

To attain this end the Expedition will visit not only those localities of known interest, but also places nearly or entirely unknown to the naturalist.

For the purposes of this Expedition there will be a thoroughly first-class steamship of a thousand tons burden, fitted with state rooms, and saloons for study, work, lectures etc., and provided with steam launches, a large number of boats and a sufficient armament, and commanded by experienced officers, with a trained crew.

There will be provided a large library and a full supply of scientific apparatus for research, and material for the preservation of specimens.

The Scientific Corps will consist of a Faculty of ten, now being organized from among the professors of the leading Universities.

Instruction will be imparted by lectures on all subjects that can be studied with particular advantage on an expedition of this kind.

Preliminary work and training will commence as soon as practicable after the vessel leaves New York.

There will be accommodations for sixty to eighty students.

As the vessel will carry no cargo other than its outfit, there will be ample room for commodious accommodations, as well as for the storage of extensive collections in natural history and curiosities.

Every facility will be afforded for study and research, and special attention will be given to the convenience, comfort, and health of all on board.

As a good table contributes materially to the health and enjoyment of such an expedition, every care will be taken to secure good cooks and stewards, and the best provisions circumstances will allow. To this end the Expedition will take every opportunity to recruit, refit, and obtain fruits and fresh provisions; this, with the great improvement in canning fruits and meats, will secure the best of diet. Ice will be manufactured on board the vessel.

It is intended that the table shall be as good as that furnished first-class passengers on the best transatlantic steamships.

The Faculty will consist of specialists in the following subjects: Modern Languages, History, Architecture Archæology, Ethnology, Astronomy, Navigation, Geography, Botany Zoology, Geology, Paleontology, Physiology, Comparative Anatomy and Taxidermy.

There will also be an experienced physician and surgeon and a chaplain; also a photographer, with proper apparatus for photographing all objects of interest; thus retaining a complete panorama of the voyage for future reference and publication.

It is expected that large and extensive collections in Natural History will be made. These collections will be one-half the property of the students and faculty, to be disposed of as they may determine, and one-half the property of the ship.

The route proposed, subject, however, to such variations as experience may show to be advantageous, is as follows: Leaving New York in July, 1877; touching at the Bahamas, Tortugas and Havana; thence to the Island of Marajo, at the mouth of the Amazon, where time will be given to explore the curious ancient remains consisting of decorated burial urns and other pottery (still almost entirely unstudied), and also for the making of collections in Botany and Zoology, for which the locality is so noted. A portion of the Expedition will ascend the Amazon.

Thence to the Straits of Magellan (touching at Rio and Montevideo, and the Falkland Islands), where some stay will be made to allow of excursions inland to study the natives and make collections; thence to Valparaiso to receive letters from home; from thence the Expedition will proceed westward, touching at several of the beautiful Polynesian Islands, famous for their delightful climate, fruits, corals and sea-shells, and monumental remains of former, forgotten races, and presenting favorable opportunities for dredging. Thence touching at Australia and at New Guinea to obtain some of the strange animals and birds of those countries.

Macassar will be visited for coal and to obtain guides for northeast Borneo, Macassar being the head-quarters of the Dutch trade with that part of the island. It is hoped by the aid of these Dutch traders (who have offered their assistance to a member of the Faculty who has just returned from a scientific tour of some years in this locality (to cross the northern part of Borneo from the east to the west side, visiting the great lake and high table-lands which are supposed to be there. There are strange stories of this great inland lake and of large animals, among them the elephant. All work done here will be new, not only in natural history but in geography and ethnology. Thence to the Sooloo group, which is almost unknown scientifically; the natives are at war with the Spanish, and are piratical, but are friendly with all speaking the English language.

The parts of the Phillippines visited will be mainly those unexplored and promising great novelties in natural history. The island Basilan will be visited from Lambauga, and trips are planned to cross the island of Mindanao in two directions, as nothing is known of its natural history or geography except in the immediate vicinity of Lambauga. No difficulty is apprehended, as villages of Christian Indians with Spanish priests are found along its coast, and these have friendly intercourse with the interior tribes. Thence to the islands of Samar and Leyte, which are scientifically unknown, although there is nothing to prevent a thorough examination, as the natives are friendly. Zebu is visited as a coaling port and for dredging, the neighborhood being rich in corals, glass sponges and shells.

Manilla is visited, as the capital of the Phillippine Islands. Within easy reach are found villages of that curious people, the Nigutos or Attas, supposed to be of Papuan origin. An excursion will also be made to the unexplored island of Mindoro. The north end of Luzon, with its rich mines of copper and gold, will be visited, as this part of the island has never been scientifically explored. Thence to Hong Kong and the great Chinese city of Canton, where sufficient time will be taken to visit points of interest. Thence to Takao, on the southwest of Formosa, which is the head-quarters of a Chinese trade in junks to the east coast. Pilots and interpreters will be procured here for that part of the island where it is known Chinese traders are living." The western portion of the island is entirely unexplored.

The peaks of the mountain range reach a height of some 12,000 feet, promising a new fauna and flora resembling that of temperate regions. An effort will be made to cross the island to the Chinese settlements on the west.

An excursion of this kind will be of great geographical interest.

Thence down the China Sea to Singapore, from whence excursions will be made to points of Archæological interest in Malacca, Sumatra and Java, and for the study of natural history. (Here, as well as at other points, students will accompany excursions most to their tastes).

Thence up the straits of Malacca to Calcutta; thence to Ceylon, the Laccadive Islands, and Bombay; making such other stops as may seem desirable, and giving those who wish to do so, the opportunity of leaving the vessel at Calcutta; making excursions through India for the purpose of studying her wonderful architectural remains; joining the Expedition at Bombay. Thence to Aden and the Suez Canal to Alexandria, from whence an excursion will be made ap the Nile. While in the Mediterranean points of most interest will be visited, including the Holy Land, Cyprus, Smyrna, Constantinople, Athens, the ruins of Troy, Naples, Pompeii, Rome, Pisa, Florence, Venice, Verona, Milan, Genoa, Gibralter and Malaga; thence to Havre, France giving ample time for those who desire to make excursions through Spain and France to Paris, stopping at points of interest on the route. From Paris excursions can be made to Bouvais, Amiens, Arras. Brussels, Waterloo, Cologne, Coblentz, Strasburg, parts of Switzerland, Troyes, Rheims and Rouen, joining the vessel at Havre. Thence to London, visiting points of interest in England. Thence to New York, touching at the Azores.

The voyage will occupy two years, and as about two-thirds of this time will be in port, it is thought that sufficient stay can be made at all places visited to satisfy the objects of the expedition.

It is estimated that the distance travelled will be about 50,000 miles.

Any localities in which there may exist epidemics will be avoided.

The students will be drilled sufficiently in military tactics and boating for self-preservation, and when on shore in uncivilized localities, they will be under military discipline.

All travelers who have made long journeys to partially civilized countries, have found that the principal hardships are from want of cultivated society, music and good food, and of proper care in case of sickness; all these will here be avoided; several of the Faculty will be accompanied by their wives or daughters. The cabin will have a piano, and a brass and string band will be organized from among the ship's company; care will be taken in selecting waiters to obtain those of some musical ability.

The Expedition will fly the flag, and adopt the uniform of the Brooklyn Yacht Club.

Students desiring to accompany the expedition can obtain further information by applying to either James O. Woodruff, Indianapolis, Ind. Prof. W. L. B. Jenney, Portland Block, Chicago. Prof. J. B. Steere, University of Michigan, Ann Arbor, Mich.

REGULAR MEETING OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS.

[REPORTED FOR ENGINEERING NEWS.]

The American Society of Civil Engineers held their regular meeting for February at their rooms, No. 4 East Twenty-third street, New York, on the evening of the 7th inst. The first business in order was balloting for new members, and the following were elected:

Members.—Frederick S. Benson, Engineer and Superintendent of Nassau Gas Light Co., Brooklyn, N. Y; Eckley B. Coxe, Mining Engineer, Drifton Pa; William C. Gunnell, Engineer of New Capitol, Hartford Conn; David E. McComb, Assistant Engineer in charge of Works west of Capitol, Washington, D. C.

Junior.—Sanford Horton, Civil Engineer, New York.

After the election of members a ballot was taken on the question of appointing a Committee to report to the Society a form of Memorial to Congress urging the adoption of the Metric System of weights and measures, resulting in a vote of 138 for and 93 against the proposition.

A lengthy paper was then read by Mr. Henry F. Walling, C. E., on Co-ordinate Surveying, in which, in summing up, he claimed the following advantages would arise from its adoption: First. The attainment of the highest practicable degree of accuracy as well in smaller local surveys as in more extensive operations. The units of measurement used by the United States Coast Survey are found, after most careful comparison with those of other countries to have a degree of precision not yet excluded by scientific skill anywhere. Second. Extreme simplicity of notation with ease and convenience of field work and computation. Third. Facility in graphical representation. Fourth. Absolute certainity of location in description of conveyances and consequent removal of a fruitful source of litigation and trouble. No change is proposed in existing methods of determining the third ordinate, *i e.*, altitude. This third ordinate is the height of the point above the level of the sea.

The paper was referred to the Committee on Library with the recommendation that it be printed.

After the reading of this paper, some facts and opinions were discussed relating to the failure of the railroad bridge at Ashtabula, Ohio, during which two letters were read, one from Mr. G. K. Warren in which he contended that the sudden snapping of the bottom chords, or of a tie, would produce the same sensations to the occupants of the cars in the immediate vicinity, as if the car had jumped the track.

Another letter was read from Mr. E. S. Philbrick giving the results of observations made by his assistant Mr. A. H. Howland.

A close description is there given of the position of the wreck; after which he continues: All the 1 beams forming the top chords, the main braces and floor beams were dragged out as soon as possible after the disaster, and irrevocably mixed. But the position of the bottom chords, vertical rods, angle blocks, etc., taken together with the evidence of the enginemen seems to indicate that the failure began by the breaking or displacement either of main braces or top chords in the second or third panel from the west end of the south truss. The floor must have sunk first on the south side as that side only was loaded and the general position of the parts of the wreck confirms this hypothesis. Diligent search was made for evidences of derailment but none were found. Some forty railroad ties were found but no wheelmarks on them. A few wheels were broken or cracked but nothing to show whether they were sound or unsound before the fall. There seems to have been sufficient elements of instability in disjointed and poorly connected top chords and main braces to account for the disaster.

Notice was also read of the next meeting of the American Institute of Mining Engineers, to be held on Tuesday evening, Feb. 27th, at 8 o'clock, at the rooms of the American Society of Civil Engineers. After which the meeting adjourned.

DETAILS OF THE ASHTABULA BRIDGE BY EDW. S. PHILBRICK, C. E.

This was a *deck* bridge, with two iron Howe trusses, each having fourteen panels of eleven feet length. The height of truss was 19 ft. 9 in. from center to center of chords; width between centers of trusses, 17 ft. 2 in.; width of deck, 25½ ft.; length between back walls, 158 ft. The bottom chords consisted each of five lines of bars each 5 in. × 1⅜ in., flat side up and side by side, each line consisting of two bars, one over the other, except that the third line drops the bottom bar in 2½ panels at ends of trusses, and the second and fourth lines drop the bottom bar in 3½ panels at ends. Rectangular lugs were welded to top bars at panel points to fit into traverse grooves of the cast angle blocks. These bars are in lengths of three or four panels. Splices were made by hooks fitted to square lugs on ends of bars and clamped by ferules driven or shrunk on. These ferules clasp the hook, the spliced and the continuous bar all at once. The angle blocks at panel points were all cast-iron; bearing faces nearly plane but not planed. L-shaped lugs were originalty cast on these faces 1½ in. long and ½ in. projection, to hold the braces in place, as these were originally put in viz., with the top and bottom flanges of the I-beams of which all the braces were composed, being parallel with the plane of the truss. We are told by men who were employed in its erection, that when first put together some wedges were drawn on the false works, the braces being in the position above described, and the braces had been clamped at their intersections and these clamps parted, allowing the braces to buckle and truss to sag. A few more wedges were drawn and it settled more, the braces getting some inches out of line. Mr. Stone was sent for and had it jacked up and the rods screwed up. The nuts could not be turned much. It was let down again on the false works and the braced turned 90° on their own axes. Additional ones were put in at the end panels, making six instead of four, and the bridge then stood. The little L-shaped lugs on the angle blocks were mostly chipped off to allow the braces to be turned, also some corners of braces, leaving them with nothing but friction to hold them in place; for what little was left of the lugs did not fit the new position of the braces. Paint marks now show them to have moved some inches out of place when last painted. The braces were all 6 in. I beams, rolled iron, with a section of 6 to 9 square inches, the heavy ones being supposed to be at the ends of trusses. Beginning at each abutment each panel had the following number of braces leaning forward toward the other abutment, viz.: 6, 6 ?, 4, 4, 3, 3, 3, 2, 2, 2, 1, 1, 1, 0. The end panel having no counterbrace, its main braces were stayed at half length by a bolt and gas-pipe strut passing to the first bottom angle block. There was no vertical end posts at the abutments. The top chords had each two of their members extending over to the back wall, where bore on rollers at one end, making a beam 12½ ft. span, composed of two six-inch I-beams directly under one rail of the track and carrying about 86 per cent. of the loads passing over this track, for the other beam was 17 ft. 2 in. distant. *The several braces of each set were connected only by a yoke of two rods of ⅝ in. diameter at their intersections at the centre of their length with cast packing pieces between them!* The vertical ties were 8 in number at each angle block 2⅛ in. diameter at ends, and varying to 1½ in. at middle of truss. They had forged heads at top, and were upset at bottom, where nuts were applied. Their ends bore against iron washer straps, which extended across full width of chords and on the bottom chord somewhat more at the inner end for connections of the lateral brace struts. These struts were railroad bars confined by a stirrup passing over top of rail and down through holes in bottom flange to bolt to the strap described above. They were applied at alternate panel points 22 ft. apart. The bottom lateral bracing was in panels of 22 feet, composed of flat bars, 2½ in. × ½ in. Their ends were hooked into recesses formed for the purpose in the cast-iron angle blocks, but they had no adjustment for length. A most unique feature in this bottom horizontal system was this, that the tie braces met at the chords at points *intermediate* between those where the struts were applied and 11 feet distant, so that if they had ever been screwed up the chords would have been pulled into a zig-zag or a serpentine line, while in their actual condition all the lateral forces arising from the wind or from the passage of trains over the bridge, instead of being counteracted or controlled, must have been *assisted* by this arrangement to break up the alignment. The top chords were formed of five lines of 6 in. I-beams, side by side, two panels long and breaking joints. Their ends abutted against cast-iron lugs on the angle blocks, 6 in. high, 5 wide and 1¾ in. thick, these lugs being omitted where the bar was continous, three at one point, and two at the next. *These I-beams were connected to each other only by ⅝ in. bolts and cast spools, two in a panel!* Instead of closely fitted end bearings they were *shimmed* at the ends against the lugs of the angle blocks. It is said this was done to give the desired camber, the top chord being cut a little short for that purpose. These shims were held in place only by friction. The weight of these 6 in. I-beams varied, their webs being from ⅛ to 1 in. in thickness. The heavy ones were supposed to have been in the central part of the length; but, as in the case of the braces, they were so scattered and mixed by the clearing of the ground, immediately after the disaster, in erecting trestles for the tracks, that little clue was left to their original position.

No broken ones were found, but they were bent and twisted in all sorts of shapes, as were also the floor beams, and all were generally completely separated by the fall. The floor beams were also 6 in. I-beams, spaced three to a panel and about 25½ ft. long. They rested directly

on the top chords, which were thereby subjected to transverse strains, by the passage of every wheel on the tracks. At alternate panel points there was a lug riveted to the bottom of a floor beam, fitting against the inner edge of the top chord, thus acting as a strut for the lateral bracing. The latter was in panels of 22 feet, composed of 1¼ in. round iron, flattened at ends and formed with a hook fitting a recess in the angle block, and held down by the weight of the top chord bars. There was no adjustment of length. A stirrup passed over the floor beam acting as strut, and confined it to the chord. There was originally only one track on the bridge, but of late years two had been used, spaced 7.20 ft. apart in clear, so the outer rails came almost exactly over the centre of the trusses. Under these rails were two pieces of longitudinal timber, each 7 in. × 12 in., and under the inside rails three pieces of same size. Another stringer lay outside, at each edge of floor. Don't know about any in middle, between tracks. The ties covered the whole width of 25½ feet, spaced one inch apart and made of oak, 3 in. × 5 in. Besides guard timbers on edges of floor, there were guard rails inside the tracks, converging to centre of track near end of bridge. This floor was better than the average of bridge floors, and if the ties were sound, as we have every reason to suppose them to have been, they would have sustained a derailed car and perhaps an engine, at least anywhere but in the middle of the width of the bridge. There was a pair of transverse vertical braces every 22 feet, made of 1¼ in. round iron, adjusted by turnbuckles. They were flattened at ends with a hook fitting a recess in the angle blocks, but were *held in place only by a top bolt of ⅝ in. diameter screwed into the castings!—The Railroad Gazette.*

CORRESPONDENCE.

NEW HAVEN, CT., *Feb. 8th, 1877.*

"SKILL AND CONSCIENCE IN BRIDGE BUILDING."

EDITOR ENGINEERING NEWS:

SIR:—In the article on "The Ashtabula Calamity," by Clemens Herschel, C. E., of Boston, published in your journal Feb. 3d, the necessity of "skill and conscience in bridge building" is well brought out; and certainly the importance of having such structures designed by competent engineers, and the construction superintended by skillful and conscientious inspectors cannot be too strongly brought home to persons and corporations contracting for bridges. Mr. Herschel also takes occasion to speak very depreciatingly of the so-called "American" practice of bridge construction, as contrasted with the "European or riveted system."

Now we take no exception whatever to Mr. Herschel's anathemas upon the use of cast iron in the principal members of bridges; nor even for joint boxes, although in certain designs for minor parts, where there is no possibility of transverse stress, we believe the best quality is not so *very* objectionable; still, it is not necessary, and may well be dispensed with, especially in railroad bridges. Neither would we have him retract one word of his disapprobation of simply butt joints and screw end main ties. But we think he might have made a clearer distinction between such structures and the well designed pin joint bridge, which has been worked up by American engineers, and has given to the "American system" its well deserved popularity.

Wrought iron posts connected to the chords with well proportioned pins, no more deserve the name of "simple butt joints," than the riveted connection, and are no more liable to displacement.

Mr. Herschel thinks it behooves engineers and bridge builders to express their opinions clearly and unbiasedly upon this question of connections; and certainly the joints of a bridge are the points that deserve the most *careful attention.* He has expressed his preference, and it is unreservedly in favor of riveted connections.

For very short spans, the riveted plate girder, when well proportioned, has never been excelled for rigidity and stability; and for very light trusses of short span, riveted work has unquestioned advantages as regards rigidity. But for long spans, and heavy bridges, the tables are turned. In such cases, the properly proportioned pin joint bridge (wrought iron throughout) we believe is not excelled by the riveted structure, and in many respects has decided advantages.

(1.) In the riveted bridge, the chords are usually built up of plates and angles, the web members riveted to the side plates, and the increments of horizontal strain at each panel point allowed for by additions to the top and bottom plates. By this arrangement the material in the chords is not symmetrically disposed with reference to the axis of strain; and the result will be that some parts may be strained more per square inch than the unit strains, and other parts less. In the pin joint bridge, one of the best forms of top chord is built up of a thin top plate and heavy side channels; thus the great bulk of the material is put where it will do the most good, and symetrically disposed with reference to the axis. In the lower chord links this result is obtained almost perfectly.

(2.) The lower chord of the riveted plan is usually trough-shaped, and catches dirt and snow, and during the winter is often filled with ice, unless covered over; thus adding to the dead weight, and doing the iron no good. With the lower chord links of pin bridges, there is no trouble of this kind.

(3.) The axes of the different members of the riveted bridge which are expected to assemble at the panel point (perhaps I should say ought to) do not ordinarily do so in all the panels. Transverse strains are thus induced which do not enter into the calculations. In the pin joint plan the different members do necessarily *all* assemble exactly at the panel point, and the strains are delivered exactly as they were intended to go.

(4.) In very long heavy spans, where the dead weight is very great in comparison with the live load, the waste of material on account of rivet holes in the tension members of the riveted bridge is very great. The weight of this *worse than useless waste* devolves additional duty on the effective section remaining, and the consequent necessary increase of the net section involves another waste. In the well proportioned pin joint bridge there is no such waste; every pound is utilized; and this is one of the principal reasons why for long spans the "American" system has competed so successfully with the "European."

(5.) On the riveted bridge a large amount of work remains to be done after it has reached the ground, and ordinarily this cannot be done nearly as satisfactorily or economically as at the factory. It usually requires a more elaborate system of false works, a much longer time, and more skilled labor to erect. These are *frequently very important factors* in the question of bridgeing; and in the pin joint system they are reduced to a minimum.

(6.) In the riveted bridge a large element of uncertainty creeps in, in the shape of hand riveting on the false works; of which a great deal is necessary. The rivet is usually smaller than the hole it is expected to fill, and unless care and pains are taken, it is possible and even probable that the shank of the rivet will not be upset its full length; and care and painstaking are commodities that under the sharp competition in this country are not allowed to be wasted in the erection of bridges. If all the rivets do not perfectly fill the holes (and it is highly improbable that they all will, as such work is ordinarily done), then such will be useless; hence some of the rivets will be strained excessively, and others not at all, and this again will complicate the strains in the connected members.

These objections apply equally to pin joint bridges, when "field riveting" is necessary; but little is necessary, and that little confined principally to cover plates in compression members, which are of but little consequence, or at least not of such *vital importance* as the connection of web members. Nearly all the riveting in the pin joint system can be done by power at the factory; and power riveting belongs in another catalogue entirely. If Mr. Herschel will devise a simple, cheap, and powerful hydraulic or other machine to do this work in the field in the most awkward positions, he will have overcome one of the obstacles to the introduction of riveted bridges.

(7.) The slightest deflection of any part of the riveted bridge, due to a heavy, concentrated load, will cause a tendency to transverse strain in the web members, and these members will act with a powerful leverage tending to shear the rivets by twisting; under such circumstances the rivets on one side of the member would have to take all the strain the load would send through that piece, and possibly considerably more. The practical effect of this tendency, however slight, to rack the rivets first one way and then the other, would be to loosen them; and this effect is intensified by the slightly diminished diameter of the shank of the rivet by shrinkage in cooling. The members of the pin joint bridge being hinged on a single large bearing, these difficulties are avoided.

(8.) The absolutely accurate fitting together of the different parts, and a consequent uniformity of strain, is not so certain in the riveted bridge—we may say almost impossible, as rivet holes are usually punched; and drilling in place is too costly for competition in this country; and where the drift pin needs to be used to draw, initial and transverse strains are again developed that cannot be computed.

It is just here that the pin joint bridge affords us a beautiful illustration of a perfect harmony between theory and practice. Each set of members or bars in each panel are all clamped together and bored *at the same time,* in a double end borer; therefore if the iron is at the same temperature (as there is only one hole instead of several as in the riveted bars), they must absolutely match; and the pin is turned to fit the hole to 1-64th of an inch. The members must all assemble exactly at the panel points of the strain diagram; the strains will therefore all be axial, and the members strained uniformly throughout their section. The engineer here knows just what he is about. He knows he will have just the strains on his diagram, and no other; and that he need not (as in some other systems) throw in a little material here, and a little there, to allow for strains that are not computable, or for imperfect workmanship.

We are well aware that *some* of the above objections to riveted bridges are not of much practical account, still, they are theoretical considerations of more or less weight, which do not apply equally to the pin joint bridge. And where without sacrifice we can make practice harmonize with theory, why not?

We believe that for long spans, the "American" bridge, taken as a whole (we mean, of course, the best American practice), is *not* inferior to the "European or riveted" bridge, nor less *reliable,* as Mr. Herschel would lead us to infer. We claim for it economy, simplicity, equal if not greater strength with the same amount of material, and a combination of all those qualities that go to make up "an iron bridge of assured safety."

A.B. HILL, C. E.

NEW YORK, *Feb. 15th, 1877.*

EDITOR ENGINEERING NEWS:

SIR.—Business continues to be very depressed and all engineering projects are affected. Still, the general feeling for the future is a hopeful one. At present very little practical work is being done and that is mostly on necessary city improvements, and the little work carried out on the East River bridge. The authorities of Brooklyn have decided to expend about $75,000 on storm sewers, giving those on contract which are to cost over $10,000. One of those proposed will cost about $10,000 and another about $25,000.

Quite a number of projected works in and around New York are talked of; among others an elevated road in the city, which is fighting for an existence in the courts. A road from Greenpoint, L. I., to Coney Island, undoubtedly for summer pleasure seekers, giving them access to the sea shore in half an hour. A second bridge between Long Island and New York is also occasionally talked of which, if built, would probably serve exclusively for railroad purposes and would be built entirely by private capital. The cities here have enough of building bridges for some time; their one attempt in that direction will satisfy them, for they find them to be expensive luxuries. The East River bridge was to have been finished in 1874, at an estimated cost of $7,000,000. After beginning the work $9,500,000 was asked for and in 1875 the estimates reached $13,000,000. The plans and estimates are not fully made yet, but, owing to the great depreciation of values in late years, the last named sum will probably cover the cost of the bridge. At present the interest on the amount expended is said to amount to about $1200 per diem, and yet the inhabitants of New York and Brooklyn have derived no benefit, thus far, from this enormous expense. It is hoped, though, that the future benefit to the two cities will amply repay them for the fearful tax now borne.

Mr. J. Lloyd Haigh, the successful competitor for the contract for furnishing the steel wire for the bridge cables, is making active preparations for its manufacture. In addition to his old works he is putting up a temporary structure 200 x 90 ft., in which the steel wire is to be galvanized. Owing to the incompleteness of the preparations very little has been done as yet in manufacturing the wire; last week ten tons were sent away. The contract requires the full supply of wire to begin on the first of April; it is expected that all arrangements for the manufacture will be completed before that time, and then about 150 tons of finished wire will be turned out weekly, giving employment to over 200 men. The wire made in these works, for the cable, is of superior quality. It is No. 8 wire, bearing on an average a load of 4,000 lbs. and stretching 4 per cent. before breakage. The contract requires that the wire should bear a load of 3,400 lbs. and stretch over 3½ per cent. before breaking. In a list of trials made, which I saw, the smallest breaking load was 3,540 lbs. which stretched the wire 4 per cent., and the greatest was 4,735 lbs., stretching the wire 4 per cent. A wire was tested in my presence which broke with a weight of 3,620 lbs., stretching it 4¼ per cent. All of the results agree very well with those of the tests made of Mr. Haigh's wire, at the competitive trial when his wire proved to be superior to any furnished by rival competitors. These results justify the wisdom of our bridge directors in awarding the contract as they did, especially as Mr. Haigh's price was below that of all rivals, viz: 8 and 7-10ths cents per lb. gold.

Experiments are still being made at Albany by our ambitious "statesmen" to legislate good government into New York city. The last thing reported is a bill about to be introduced, which proposes to reconstruct all the public departments in New York. By it the Dock Commission is to be abolished and all its powers and duties vested in the Department of Public Works. The Department of Buildings is to be merged in the Fire Department and the street cleaning is to be taken from the Police Department and put in charge of the Commissioner of Health. Like many of its predecessors this bill will doubtless be buried in some legislative pigeon hole, never to be resurrected, and all its good and bad points will soon be forgotten.

E. A. R.

COMPARISON OF IRON AND COMBINATION BRIDGES AS TO THEIR ECONOMIC MERITS.

EDITOR ENGINEERING NEWS:

SIR.—The testimony in regard to the Ashtabula disaster shows that while the tensile members of that structure were strong enough, those subject to compression were weak.

This fact proves nothing except that the bridge was not carefully designed, or more probably not constructed as designed; yet it is an exemplification of the tendency

BRIDGE AT PLAINFIELD, N. J. BY THE AUTHOR. 104 FEET SPAN; 25 FEET ROADWAY; 8 FEET SIDEWALKS; 100 POUNDS PER SQUARE FOOT; FACTOR OF 5 FOR SAFETY.

to push economy to dangerous extremes in proportioning the thrust members of a bridge. The temptation so to do is great in iron structures on account of the inordinate weight of their compressive as compared with the tensile members.

With a view of determining the facts as to the cost of using wood in compression in combination with iron in tension in bridges, estimates were obtained from a company engaged in building both styles of bridges as to the cost of each. Each to be of same span, strength, etc., and to contain same quality of iron. Also an estimate of cost of renewing the entire woodwork of the combination bridge on the supposition that the track must be kept in condition for the passage of trains during said renewal; below are the figures

For the Complete Iron Truss	$9,000.00
" " Combination	6,300.00
Difference in favor of latter	$2,700.00

To replace entire woodwork of Combination bridge, $1,800.00, including labor and provision against delay of trains.

These figures furnish the necessary data for comparing the two systems of construction. In making this comparison there must be considered, the interest on money invested, the cost of renewals, and a renewal fund sufficient to keep the truss in perpetual repair.

The interest on first cost is a factor in the problem because the total cost of a structure at any time is made up of the original expenditure added to the accrued interest. If built on borrowed money interest must of course be paid; if otherwise, the money could have been employed in some other investment which would have returned interest. This interest in the nature of things will be compounded annually.

The periodic renewals of the Combination will be provided for by a sum of money (in the manner of a sinking fund) which improved at compound interest will, during the intervals between renewals, amount to itself plus a sum sufficient to make the renewal. This in the following discussion will be called the renewal fund.

To express the relations of the quantities by formula which will be of general application, let

x = original cost of Iron Bridge, Vi total cost at any time.
c = " Combination, Vc " "
d = difference of cost $= x - c$
r = value of money in per cent. per annum.
p = cost of renewal.
t = number of years between renewals
a = renewal fund.

Any sum of money at compound interest in t years will amount to $p(1+r)^t$ Eq.(1)
in which p = the principal.

In consideration of the above reasoning the following formulated statements will be true

$Vi = x(1+r)^t$ Eq.(2) $Vc = c + a(1+r)^t$ Eq. (3)

Therefore at the time of construction for equal economy x must equal $c + a$.

Again at the time of renewal the total saving effected in the time t by the adoption of Combination in preference to Iron, must equal

$x(1+r)^t - c + a(1+r)^t$ Eq. (4)

Furthermore the renewal of the Combination can be made (and no greater expense incurred than the original construction of Iron would have involved) as often as the difference between the cost of Combination and Iron at compound interest becomes equal to itself plus the cost of removal, or whenever

$d(1+r)^t = d + p$ Eq. (5)

To apply these formulæ to case in hand the following assumptions will be made:

1st. That as regards painting and incidental repairs the two trusses will be on an equal footing.

2d. The Combination will require renewal every twenty years; this, considering that the timber is used solely in compression, and that the upper chords can be completely protected from weather action, is moderate and justified by experience, then will "t" = 20 years.

3d. That the rate of interest will be 7 per cent. Few railroads borrow money at so low a rate. Then will "r" = 0.07.

We do not yet know the value of "a" but it can be readily found from our formula. The amount which "a" must equal in twenty years is the cost of renewal plus itself (*i e*) $1,800 + a. Therefore from (1)

$1800 + a = a(1+r)^t$ whence $a = \frac{1800}{(1+r)^t - 1} = \$627.20$

"d" will equal $9,000 - 6,300 = $2,700.00

From 2 and 3 we find for equal economy the Iron truss should cost $6,300 + $627.20 = $6,927.20 instead of $9.000.

From (4) we have $9,000 × $1.07^{20} = $34,830.00$ for total cost of Iron.

From 4 we have $6927.20 × $1.07^{20} = \frac{\$26810.00}{\$8020.00}$ for total cost of combination. Showing a saving in twenty years of $8,020.00 by the adoption of Combination bridge.

From (5) we get, using logarithms for convenience of calculation.

$$t = \log.\frac{(d+p) - \log. d}{\log.(1+r)} = 7.55\text{-}100$$

That is to say every seven and one half years the Combination can be renewed without loss of money.

The formulæ by the aid of logarithms are very easy of application and afford a rapid method of comparing structures under like conditions.

The above comparison is made on the basis that the Iron bridge will last for all time. But there is a circumstance which must not be lost sight of, that is, that all bridges are liable to accident; the substructure may be undermined and destroyed. In extraordinary floods floating snags may carry them away. A derailed train may cut away the bracing and let the structure down, in short, innumerable contingencies may arise which would result in the destruction of a bridge. In any of these cases the loss on the Combination would be light, while that on the Iron truss would be heavy, amounting in most cases, to two-thirds the first cost. In one case of personal observation the cost of restoring an Iron bridge, so lost, exceeded the original outlay. This arises from the fact that the tensile members are usually merely bent, but can be straightened and used again, while the compression members of the Iron truss are so broken and deformed as to be well nigh worthless except as scrap iron.

With the above showing none need hesitate to build the combination truss from a monetary point of view. But to assert that Combination bridges should, therefore, always be built in preference to Iron would be absurd. In certain localities many considerations will determine in favor of Iron; still there are many situations in which the Combination bridge could with great advantage be adopted. V.

HIGHWAY BRIDGE AT PLAINFIELD, N. J.

The above illustration represents a bridge designed by Alfred P. Boller, A. M., C. E., the author of "BOLLER'S HIGHWAY BRIDGES," and used in his valuable work, a notice of which is given below.

BOOK NOTICE.

IRON HIGHWAY BRIDGES: — Practical treatise on the Construction of,—By Alfred P. Boller, A. M.

Iron bridges are becoming very numerous throughout the cities and counties of our Northern States. These structures are generally bought by parties who are not competent to judge as to what they are purchasing, and who seldom call in the services of an expert to decide for them and to see they obtain what they need. The bridges are sometimes sold by contractors who do not intend to supply a first-class article. The trusses which may be seen here and there, on any short journey, are sufficient witnesses of this fact to the trained eye. That they do not collapse is due to the generally light loads to which they are subjected.

Mr. Boller has pointed out in this book "the peculiarities of material and construction involved in the designing and building of Iron Highway Bridges, in the hope that a dissemination of their scientific principles in a popular form, will bear fruit in a more thorough appreciation of a noble art, and in elevating the standard of requirements of this very important class of public works;" and he has dedicated it "to town committees, selectmen, county freeholders, and other public officers, to whom is entrusted the responsibility of erecting Iron Bridges."

In the last enumerated class will come those surveyors and engineers who, not experts and not thoroughly acquainted with the details of this branch of engineering, are called upon, as county surveyors, or local engineers, to give their assistance and opinion in regard to a proposed bridge. To such persons, and indeed to everyone whose business does not lie exclusively in this line, we can heartily commend the book, for every section contains excellent instructions and advice. The second part is devoted to determining the strains in the ordinary forms of trusses in an elementary manner; it will be easily understood and very serviceable.

One piece of advice which the author gives has pleased us very much: "To ignore any plan of bridge that cannot accurately be analyzed as to the character and amount of strain occurring in all its parts." He gives some valuable information about eye-bars and pin connections and comments on riveted trusses. The only points to which we object are in relation to the bowstring girder. We do not agree to the statement that this type "is properly not a truss at all, but simply an arch wherein the horizontal tie takes the place of fixed abutments." Then we should have been glad to see the bowstring girder more treated fully, for it is a type of truss much used for highway bridges, and therefore one which the reader would especially desire to be informed about. Mr. Boller states that there are no strains on the diagonals of this truss when the bridge is uniformly loaded, and omits to mention that this is the fact only when the panel points of the bow lie in a parabola. Indeed, he says nothing about the curve; in the example worked out, the bow is neither parabolic nor circular.

Annual Report of the officers of the City of Allegheny, Pa., for the year ending December 31, 1876.

Journal of the American Society of Civil Engineers for January, 1877.

Annual Report of the Board of Trade of Minneapolis, Minn., for 1876.

NOTES.

The Louisville Bridge Co. has declared its usual six months' six per cent. dividend, payable Feb. 15.

In ten days another test of the West Side pumping engines will be made, under the direction of Messrs. Lane, Haswell and Warrington.

The Lehigh & Wilkesbarre Coal Company of Pennsylvania have applied for a receiver. It is thought the mines will be worked as usual.

The City Council of Fort Wayne, Ind., at their meeting on the evening of the 13th inst., passed a resolution postponing the special water works election, set for the 20th inst., until next May.

It is proposed to cut a broad canal from Manchester, in England, to the river Mersey. Manchester hopes to have a port of entry, accommodating vessels of 4,000 tons. A ship canal is also projected between the North Sea and the Baltic.

The Board of Trustees of Princeton College have elected three new professors:—Professor C. A. Young, of Dartmouth College, in astronomy; Professor Charles G. Rockwood, of Rutgers College, in mathematics; and Professor S. C. Oris, of Marietta College, Ohio, in Greek.

Sobrero considers two operations in the manufacture of dynamite exceedingly dangerous, namely, the mixing of the nitro-glycerine and the infusorial earth, and the pressing of the mass into moulds to form cartridges, as in either case an explosion may be produced by friction and pressure.

M. Mouchot is continuing his experiments in utilizing the heat of the sun. He has lately shown to the Paris Academy of Sciences a small still, in which the sun's heat was applied to the processes of distillation. With this still, the mirror of which was twenty inches in diameter, the inventor succeeded in distilling a quart of wine in half an hour.

Owing to the large number of emigrants from the old country forwarded by the Canadian emigration agents in Manitoba and the Northwest Territory being diverted from their route at Duluth by American agents, and induced to remain in the States, the legislature of Manitoba have petitioned the Dominion government to appoint an agent at Duluth for their protection.

Viehoff has described very favorable results from using gum joints for gas pipes. On taking up pipes that had lain in tolerably damp earth for eight years the gum rings were found to be perfectly elastic, without any indications of decomposition or softening, and they adhered so firmly to the iron that it required considerable time for four men to work the pipes apart, and in some places the gum separated instead of leaving the iron.

A petition presented to the Common Council shows that there are 55,000 unemployed laborers in New York, and that their families number about 220,000 persons, who are reduced to great destitution. The Council has asked the Legislature to pass a law authorizing an appropriation of $1,000,000 for repairing the down-town streets, now in bad condition, in order to provide these men with work. The relief societies are all overtaxed, and there has never been so much want in the city as at present.

The Secretary of the Metric Bureau writes very confidently in regard to the early adoption of the decimal system of weights and measures by the people of the United States. He says the interest in the subject is increasing every day. The substitution of the meter for the yard, and the liter for the quart, is one of those reforms which will take time; and when adopted the people will stand amazed at the fact that the introduction of a system so simple and convenient was delayed so long.

The Baltimore Iron Bridge Company has just completed an iron bridge over the Conewago creek, near New Oxford Adams county, Pennsylvania. It is on the Hanover Junction, Hanover & Gettysburg R. R. Two wooden bridges had been constructed on this road within twenty years, costing about $6,000, while this iron bridge only cost $4 0.0.

The Cincinnati Bridge Co. will soon commence the construction of the bridge over the Little Miami river on the Cincinnati & Portsmouth road, (narrow gauge) The company have just closed a contract for a county bridge at Kingston, N. Y. They are now engaged on a number of county bridges two of which were recently shipped; one to Topeka, Kansas, and one to Kokomo, Indiana.

Capt. Barrett, commanding the United States steamer Plymouth, having made a thorough examination of the Eads jetties at the mouth of the Mississippi river, reports the result to the Secretary of the Navy. The conclusion of the report is as follows: "The jetties are a perfect success. At a little expense the current which now tends to the Southwest Pass and forms an eddy, can be obviated and directed to the proper course. I hope the Department will approve of my taking the responsibility of testing the success of this work with a Government vessel." Capt. Barrett further says that at the time he passed through the jetties his vessel was drawing 17½ feet. The lower jetties were passed in eighteen minutes. The greatest depth of water found was thirty feet, and the least eighteen feet, and that too, in mid channel. The upper jetties were passed in eighteen minutes and fifteen seconds. Capt. Barrett was sent to New Orleans to assume command of the naval station at that port, and act in concert with the military forces of the Government in case of trouble. He has, as he reports, taken command and opened communication with Gen. Augur.

RAILROAD NOTES.

Bonds are to be issued to complete the Waynesburg & Washington R. R., Pa.

The Kellogg Bridge Company, of Buffalo, N. Y., have an order for five spans of iron bridges for the Houston & Texas Central R. R.

A survey is being made of the proposed line of the Toledo & Ann Arbor R. R. to Owosso, Michigan. It will cross the Chicago & Port Huron R. R. at Antrim.

The board of directors of the Missouri, Iowa & Nebraska R. R. Co., have held their annual meeting, and voted to commence work at once and push the road through to Nebraska City without delay.

The *World's* dispatches from Arizona speak of more mineral discoveries near Prescott, causing much excitement. It is also reported that a railway company, to build from Prescott to the line of Sonora, has been formed with a capital of $10,000,000 in $100 shares.

A Tucson, Arizona special says the Southern Pacific railroad bill was reported to the House from the conference committee and passed. It provides for exemption from taxation for years, and permits fixing its own tolls at not more than 10 cents per mile for passengers and 15 cents per ton per mile for freight.

A railroad meeting was recently held at Dubuque, for the purpose of furthering the interests of the Sioux City, or Northern Branch of the Pacific R. R., and its extension to the Black Hills. It is claimed that the original bill provides for this branch road, and its restoration to public notice is energetically urged. Measures are to be taken to have the matter properly brought before Congress, and the work pushed forward if possible.

During the past three months 700 tons of new rails and 100,000 new ties have been put on the St. Louis, Rock Island & Chicago road, the work being done by a special construction train put on for that purpose. It is estimated that 300,000 new ties and 2,000 tons of steel rails will be put in during the coming summer. About one-half of the ties will come from Southern Illinois and are to be delivered in East St. Louis, while the balance will be procured along the line of the road.

Not many months ago a municipal Paris deputation went to London to examine the underground railway. It has now been decided to build a similar network under Paris at a cost of 160,000 000 francs. The Seine will be crossed by two tunnels, one for up line, one for down, each enclosed in brickwork, surrounded by tubes of plate iron measuring over eighteen feet in diameter.

The Chicago, Danville & Vincennes R. R., which was sold at auction on foreclosure of the first mortgage committee representing the bond-holders. The price in Chicago, a few days since, was purchased by a paid was $1 450,000. The total indebtedness of the road is over $7,000,000, but by the terms of the decree of foreclosure this is all cut off, and the present purchasers get the road clear. It is expected that they will reorganize the company and operate the road.

Within the past week parties at the head of the movement for constructing a railroad from Quincy, Ill., to Beardstown have raised sufficient funds to defray the expenses of the final survey and location of the road. On February 13th the subscribers to the location fund held a meeting, at which it was decided to have the work commenced immediately. Engineers J. E. Blunt and C. W. Irish have arrived in Quincy, and the engineering party will be organized at once, and will commence the work of locating the road at once, after which arrangements will be perfected to begin the grading.

It is believed that the Central R. R. of New Jersey must go into the hands of a Receiver, and the question of dropping its stock from the list is under consideration. The stock fell to 18½, closing at 19¼. A year ago it was 117. At the Company's office it was stated that the fresh decline on February 10th was without just reason, and that no transfers have been made, notwithstanding the large quantities reported to have been sold. There is little confidence left, however, in the management, and Wall street was full of rumors all day. As a last appeal the Company has sent out circulars asking stockholders to subscribe without guarantee towards its new certificates of indebtedness. To add to the embarrassments, the engineers announced an intention to strike on the 12th inst. unless they were paid back wages, which they claim from November, and which amount to $160,000.

The St. Louis Railroad Journal says: The building of the great railway from Vera Cruz to the city of Mexico was a colossal feat in constructive engineering. The intervening country was superbly beautiful, and crossed at right angles by the great Sierra mountain range, through which is one continued panorama of beauty. The railway is 267½ miles long, has eighteen lengthy tunnels and many fine iron bridges. It cost the grand sum of 40,000,000 Mexican dollars, and is undoubtedly the finest constructed railway on the American continent. The first forty miles is straight, and on a gentle grade, rising slowly from the sea; then, for a distance of seventy-five miles, it crosses over three distinct ranges of mountains, each of which stands up like a colossal staircase. This section is very crooked. Winding around the numerous canons in the mountains, the train runs for many miles over the very brink of precipices, almost perpendicular, 3,000 feet. The grades are 400 feet per mile. The company use an English engine—known as the Farley patent—which carries ten loaded cars with ease. It is a double engine, or two engines connected, with their heads turned together, and thirty-inch drivers. At the west end of this division, which is at Boca del Monte, the road-bed reaches its greatest elevation, which is 13,000 feet above the sea at Vera Cruz; from there it gradually declines through a continuation of broad valleys to the city of Mexico. These valleys are from three to twenty miles wide, entirely hemmed in by tall mountains. Every foot is irrigated, and in a thorough state of cultivation.

A CORRESPONDENT, one of the leading bridge builders of the country remarks of the Ashtabula bridge;—"The characteristics af that unfortunate structure are becoming pretty well known. It seemed to have been built in defiance of some of the first principles of the art."

ARCHES;

CONSIDERED GRAPHICALLY.

[Copyright 1877.]

(Continued from page 42.)

28. Recalling the three conditions of equations (4.) (6.) and (7.) it will be evident that, while it will be possible to adjust the two lines of the curve of equilibrium to their proper position by successive trials, it will not, as in the former case, be easy. The three ordinates A I, G N and B L can, however, be computed quite readily, and the remainder of the process is very simple. The statements so far made apply to a structure of any outline, so long as it acts as an arch, although some modification will be called for when the cross-section and the depth vary very much, or when what is known as the moment of inertia is not practically constant; but, for forms other than regular curves, the application of these conditions must probably be made by trial.

29. Before taking up for treatment any arches of special curves, we will notice the simple case of a rib, of any form, hinged at both ends and the middle, or, as it is sometimes called, the "three hinged arch." For such an example it has been stated that the curve of equilibrium is at once definitely located. If a single load is placed at K, on the arch A D B of Fig. 5, hinged at A, D and B, one of the two straight lines composing the curve of equilibrium must, starting from A, pass through D, while the other, starting from B, must meet the former on the vertical line drawn through K, as required by §1; A C B therefore is the curve. If 2-1 represents the weight at K, and 2-0 and 1-0 are drawn parallel to C B and A C, 0-3, drawn horizontally, will give the horizontal thrust, while 1-3 and 3-2 will be the vertical components of the reactions at A and B. Let it be remembered that the total reaction of the abutment at A is, and is in the direction of, 1-0, although it is often convenient to decompose it into P_1 and H.

A load vertically below E will similarly have for its curve of equilibrium A E B. For different positions of the weight between D and B, all of the vertices of the curve will plainly be found on the straight D L, and the portion A D does not change for any movement of the weight on the right half of the arch. A weight on the left half would simply reverse the diagram. The dotted lines show the curves of equilibrium for a weight at such successive points as divide the half span into five equal horizontal parts, and the corresponding changes in the value of H will be seen in the stress diagram on the left.

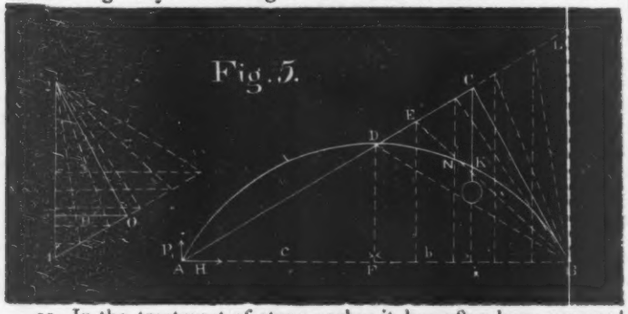
30. If the height or rise of the arch, F D is denoted by k, the half span, A F = F B, by c, and the horizontal distance F G, from the weight to the middle of the span, by b, we shall have A G = $c+b$, and G B = $c-b$. From the similarity of the triangles A D F and 013 we may write

$$3\text{-}0 : 3\text{-}1 = c : k, \text{ or } H : P_1 = c : k.$$

By the usual rule, $P_1 = \frac{c-b}{2c} W$; therefore,

$$H = \frac{c-b}{2k} W \qquad (8.)$$

The quantity $c-b$ is to be understood to mean the horizontal distance from the weight to the nearer abutment. H is seen to decrease regularly as the weight moves from the middle of the span.



31. In the treatment of stone arches it has often been assumed that the curve of equilibrium passed through either the middle of the depth of the keystone or some other arbitrary point within the middle third of its depth, and a similar assumption would then be made for the springing points. Such a treatment immediately reduces the stone arch to this case, and the curve of equilibrium can then at once be drawn. As such an assumption does not seem to us warranted, it is not expedient to go into the case of the stone arch until later; but the reader who desires to look up such a mode of handling the problem is referred to the paper by Wm. Bell, already cited in § 22, where he will see how the curve of equilibrium for a definite load is constructed, the distribution of the load found which shall make a particular arch in equilibrium, and how oblique or normal forces may be taken account of.

32. We will, however, as an example, show how to draw a curve of equilibrium for an arch which is loaded uniformly along the curve. Such a distribution will conform quite well to that of the steady load on an arched roof. For definiteness, let the pointed arch of Fig. 6 be of 80 feet span, 40 feet rise, the two arcs having a radius of 60 feet, and let it be loaded with 500 pounds per foot of the rib. We may, if we please, divide the rib into a convenient number of equal portions, which divisions will give us a number of

equal weights to be laid off on the load line. Otherwise we may space off a number of equal horizontal distances. In either case, the load of each space will be considered as concentrated at its centre of gravity, and, if the spaces are small enough, the centre of gravity may, without sensible error, be taken as coinciding with the middle of each space. For the sake of reducing the number of lines, so as to prevent confusion in our small figure, we have divided the half span into four parts, of ten feet each, measured horizontally, and their centres of gravity will be assumed to be at five feet, fifteen feet, etc., from the point of support. Draw verticals through these centres of gravity, D, E, F and G.

To find the weight on each division:—The lengths of the several portions of arc may, with sufficient exactness, be considered as the same with the lengths of their chords, which chords are perpendicular to the radii which pass through D, E, etc. If then the load on ten feet is 5,000 lbs., draw $a\,b$ horizontally, and equal, by any scale, to this amount; then will $b\,g$, $b\,f$, $b\,e$ and $b\,d$, drawn parallel to the respective chords, give the amount of load on each division, or at the successive points G, F, E, etc. Upon scaling these amounts we may lay them off upon a vertical line, from 1 to 5. In order to cause the curve of equilibrium to separate from the rib sufficiently to be easily seen in this small figure, we have taken the liberty of doubling the load on D, thus making it 4-6, in place of 4-5. The loads will therefore be, successively, about 5,400 lbs., 5,900 lbs., 7,000 lbs., and $2 \times 10{,}000$ lbs., or 20,000 lbs., from G to D, and from 1 to 6. Since $H = \frac{c-b}{2k} W$, we have for its value,

$$\tfrac{1}{2} H = \frac{35 \times 5400 + 25 \times 5900 + 15 \times 7000 + 5 \times 20000}{80} = 6769 \text{ lbs.}$$

If the given load were unsymmetrical with regard to a vertical through C, it would be necessary to calculate the two vertical components of the reactions at A and B, or P_1 and P_2, the reaction at B being laid off from that end of the load line which had measured on it the load nearest to B, and then to draw a horizontal line from the point of division between P_1 and P_2, on which to lay off the value of H. But, if both sides of the roof are loaded alike, half a diagram and half a curve of equilibrium will be sufficient. The load on the half arch being 1-6, 6-1 will be the vertical component of the reaction at B, and H will be laid off on the line 1-0. Since we have calculated H for only one half of the entire load, the above quantity must be doubled, and the total horizontal thrust will be 13,538 lbs., which is plotted from 1 to 0, the direction of the resistance of the abutment at B. The reaction at B is therefore 6-0.

As this is the first example, it may be well to pause here and renew the caution to the draughtsman to lay off the polygon of external forces in the order in which the forces are found in going round the arch or truss; otherwise he will fail to make his curve of equilibrium close on the desired point. Thus, beginning at G, he will have the weights at G, F, E, etc., or 1-2, 2-3, 3-4, etc., plotted, one after the other, down the vertical load line in the direction of their action, until the point B is reached, for which he draws 6-0, from 6 to 0. Then the point A gives a similar line from 0, slanting upwards towards the right, and the remaining loads on the left half of the arch come down a vertical line and close on 1, the starting point. The decomposition of 6-0 into 6-1 and 1-0 does not alter the case. If we had gone round the arch in the opposite direction this stress diagram would have been reversed, or turned round 180°.

Nothing remains but to draw, first a line from B to the vertical through D, parallel to 6-0, then one, parallel to 4-0, from the end of the last line to the vertical through E, and so on, the last line, parallel to 1-0, passing through the hinge at C as required. The curve on the side C A will be exactly similar. It is well to have the points of division quite numerous. The maximum ordinate between the rib and the curve of equilibrium, multiplied by H, gives the maximum bending moment.

(To be continued.)

THE WATER FRONT OF NEW YORK.

The State Legislature of 1870 organized a Department of Docks for the City of New York, vesting the power in the hands of five commissioners, who should determine upon a plan for the permanent improvement of the river line, should administer on all the wharf property belonging to the city, and should regulate the whole water front. Other legislative acts had previously passed, giving power to the city to build wharves, bulkheads, etc.; but this was the first step towards the adoption of a plan of permanent improvement. Wharves and bulk-heads had been previously erected with piles or cribs filled with stone, but they decayed, slid into the river, overturned and got out of repair generally, so that they were not even temporarily satisfactory.

The engineer appointed by the first board was Gen. Geo. B. McClellan who devised the system and method of procedure which has since been acted upon. He proposed "First. To construct a permanent river wall of *beton* and masonry, or masonry alone, so far outside of the existing bulk-head as to give a river street 250 feet wide along the North river, 200 feet wide on the East river from the Battery to Thirty-first street, and 175 feet wide north of that point. Second. To build piers projecting from the river wall, of ample dimensions, adequate construction, and, so far as possible, affording an unobstructed passage for the water. Third. Whenever it is necessary, to cover these piers with substantial sheds, suitable to the requirements of each case."

This plan was adopted by the new board of the Department of Docks in 1873, upon the recommendation of Gen. Chas. K. Graham, then the Engineer-in-Chief. The river wall is composed of *beton* blocks weighing from 25 to 50 tons each, extending from the foundation to within about two feet of low water mark, and above that line of a granite ashlar facing, backed with concrete. The foundation is either of rip-rap or piles as circumstances requires. Rip-rap is leveled over with broken stone and a layer of concrete about a foot thick is laid and leveled off by divers. Piles are cut level with a circular saw and packed closely with broken stone and concrete.

The construction was commenced between Christopher street and W. Eleventh street, together with some wooden piers, this being the most northerly portion projected at present, and also at the foot of Battery Place. The wharves are intended to be generally of wood, sheathed and protected from worms and decay. Some work has also been done at Canal street. The commercial organizations in New York, interested in these improvements, having apparently become dissatisfied with their progress and the expense of the same, have been holding meetings, during the latter part of last month and the first of the current month to take into consideration the existing condition of the docks. A report of a committee taxes the present Department with extravagance and calls for a change. A second committee advocates reducing the width of West street from 250 to 200 feet, except between W. Eleventh and Canal streets, where portions of the stone bulkhead are already finished on the 250 feet line, having in view the saving of expense in filling, and the importance of leaving the river-way as unobstructed as possible; it urges that the width of the water street on the East river should be fixed at only 100 feet; and then it advocates double track freight lines on these streets for the use of all railroads having depots in the city. What the committee reports about stone bulkheads is as follows:

"We insist, further, that if these improvements are to be of practical value to the commerce of the city, and we believe them to be of the first importance, they must be completed with expedition as well as at moderate cost.

The plan under which the Department of Docks is now pursuing its labors, and which calls for stone bulkheads, would require at their past rate of progress of about 500 feet per annum, over one hundred years for its completion between Sixty-first street, North river, around to Fifty-first street, East river, the portion of the city covered by this plan. Such a plan is evidently too slow to meet present emergencies, and this, in our view, is precisely as fatal to its usefulness as the overwhelming cost of the stone bulkhead which it demands. We therefore recommend that the Legislature be petitioned for the repeal of this plan. This committee entirely coincides with the report of your Committee No. 1, in the belief that no better bulkhead is needed than is made by wooden cribs filled in with stone. Such a bulkhead can be rapidly built and at small cost. It is very durable and readily admits of repairs when necessary. This committee believes that with a bulkhead of this character the work of widening West street, which should be the first to be done, could proceed at the rate of 2,500 running feet per annum without interfering too seriously with the commerce of the port and without devolving too great a burden upon the city. This would be a rate of progress five times as great as with stone bulkheads, and, according to the figures given in the report of your committee No. 1, it would be achieved at less than one-half the expenditure required by the present plan for covering one-fifth as much space.

The present Dock Commission came into office in May, 1875. The president is Mr. S. H. Wales, and the Chief Engineer, Geo. S. Greene, Jr. They both deny the charges of extravagance. The first sub-committee found fault with the construction of stone wharves or piers. To this President Wales answers that when the present commission went into office it found the work laid out and partially accomplished.

"It was never intended by the original Commissioners to build any stone piers except the one now building at the Battery, and a corresponding one on th East River just above the South ferry. These two piers were to be a sort of title page to the rest of the work and afford an agreeable and beautiful appearance, together with the Battery wall, to those who came up the bay and visited the city for the first time. The pier No. 1, instead of costing over $1,000,000, as stated by the sub-committee has really cost but little over $600,000. It would have been finished in December last, but for the fact that the frosty weather intervened and stopped the operations. The main thing now to be done is to cover the surface with suitable material to stand the wear and tear of the trucks and other vehicles which will pass over it. The Engineer-in-Chief of this department has thought that asphalt would be the best material, and as soon as the weather would permit the work will be continued and completed. As a commercial property I do not regard pier No. 1 as possessing a very great value. The south side during the inclement season is useless for vessels, and on the north side, owing to the rock formation upon which the pier stands, there is not sufficient depth of water for vessels of the largest capacity. I also absolutely deny that the bulkhead wall cost any such sum as stated by the committee in their report. In reality the cost was less than one-third of that amount. The Commissioners have never intended to incur any such large expense as that report states by building the wall over the distance mentioned.

"It was the original intention to construct the masonry wall along the line of the water front, from the foot of W. Eleventh street on the North River to the foot of Grand street on the East River, where the largest commercial business of the city is concentrated. At the lowest calculation consistent with the proper regard for the interests and convenience of commerce, the expense of this construction would be distributed over a period of not less than ten years. It was never proposed to continue the work above W. Eleventh street on the North River or Grand street on the East River."

"Under a new and improved plan suggested by the present Engineer-in-Chief of the department, Mr. George S. Greene, Jr., the department is now constructing a masonry bulkhead from the foot of W. Eleventh street to the Battery, at an estimated average cost per lineal foot of $225. The sub-committee referred to recommend as a substitute for the masonry wall a wooden bulkhead, at a cost varying from $110 to $150 per lineal foot. No wooden bulkhead suitable for the purpose can be built for less than $150 per foot, which is within $75 of the cost of a masonry bulkhead, which would last for thousands of years."

"The difference between the time required for the construction of the masonry bulkhead as adopted by the Dock Department and that required for the construction of a wooden bulkhead of a suitable character, would be very little, as it is impossible to divert from commercial use at any one time any considerable amount of the bulkhead and pier accommodation within the limits of the district specified."

We should be very sorry to see a much needed improvement hindered, changed in plan and rendered abortive. So much of the work as has already been executed, has been carried out in a very thorough manner so as to make an exceedingly durable and handsome river wall; and, if the new improvements are made only so fast as the public interests require, but are substantial as far as they go, the burden of well directed expenditure may be so distributed over many years as to bear lightly on the citizens.

THE letter of Mr. Clemens Herschel which we reprinted from the *Boston Advertiser* in the NEWS for Feb. 3, was also copied by the *Railroad Gazette* from the same source, so that, although not originally published in an engineering paper, it has now been quite thoroughly laid before the profession. As a natural consequence, we find several letters in reply to one portion or another of his remarks. The editor of the *Gazette*, in commenting upon a communication of Mr. T. C. Clarke, recommending the appointment of a Government board of bridge inspectors which he suggests should be selected from the corps of U. S. Engineers understands that Mr. Herschel "could not conscientiously permit the erection of the pin-jointed bridges which most American bridge-builders prefer," if he should be one of such inspectors. To this Mr. Hetschel replies in the *Gazette* as follows:

"I think your editorial of Feb. 2 does my opinions alike too much and too little justice or credit. I do not object to the *pin-joint*, especially not in diagonals. But pin-joint is not the proper name for the article. Under cover of that name we are told to swallow plain butted, or cast-iron joint-box compression joints, the use of bolts and nuts that are forever rattling loose, where rivets are evidently better, cross-members laid on, when they should be firmly riveted to, the main trusses, and much more of an unwholesome character. *Let us call things by their right names*, and then judge them according to the evidence."

We copy this note because some of our readers may have understood Mr. Herschel in a similar way. We think he was not quite clear in his expressions, and might have been easily understood to object to pin-joints. The original letter has also aroused Mr. Fred. H. Smith, of the Baltimore Bridge Co., and Mr. Alfred P. Boller, who strongly dissented from Mr. H's views in the *Railroad Gazette* of the 9th inst., and later Mr. Chas. Bender, who inserts a very able article in the issue of the 16th inst. We mention these communications for the benefit of those of our readers who take an interest in such a discussion, as it would take up too much of our space to cite them here, and they can be readily found in the well known columns of our able contemporary.

MR. EDWARD S. PHILBRICK, sends to *The Railroad Gazette* some additions and corrections to the information about the Ashtabula bridge, which we copied last week.

A HOWE truss highway bridge at Elgin, Ill., having a span of perhaps 80 or 90 feet, has braces which are largest at the middle of the span, and counters largest at the abutments.

THE communication on "Cements and Concretes," which is begun on this page, will, we trust, be of interest to all engineers who have to deal with masonry construction. It is written by one who has had several years continuous experience in dealing with these materials, who draws largely from that experience, and knows whereof he writes. Therefore the facts, results and proportions given may be relied upon.

THE plan of using iron for the construction of the frames, etc., of railway cars seems to be gaining in favor, and is remarked upon in many of our exchanges. The National Tube Works, of McKeesport, Pa., are building a number of cars under the LaMothe patent, using wrought iron tubes and steel rods for the frames and trussing. As will be noticed in our review of Mr. Higinbotham's report last week, iron has been employed in car construction in North Germany and in Austria, with good results. Box cars with iron sides have been used on the New York Central R. R., and we have wondered whether the platform cars used by Barnum last year, in his travels through the States, were not built under the LaMothe patent.

CEMENTS AND CONCRETE.

BY BERNARD R. GREEN, C. E.

(Written for Engineering News.)

It is related that, many years since, a foreman on a well known public work "down east," with a laudable aim at economy and an eye to employment for his crew of laborers during an approaching winter, innocently petitioned the engineer officer in charge to be allowed to make up and store, (!) for use the following summer, a considerable quantity of concrete. Though this was clearly a case of temporary loss of sense, it may, as an extravagant example, serve to illustrate how far it is possible for the prevalent ignorance of the laws of induration of mortars to lead ordinary workmen into absurd blunders. Men were formerly more disposed to be guided by the rules of their fathers in this matter than to study and scientifically pursue methods that would make desired results certain. Far too generally the "mortar man," foreman of the pug mill," or whatever the title of the man entrusted with the preparation of the mortar, was an ignorant laborer, who, though wielding the hoe and shovel with admirable grace and skill, possessed no proper understanding of that most essential process

over which he held full sway, and who was therefore guided only by whim in bringing the material to what he considered the proper "temper." Uniform results were often wanting, and the cause of the failure was little suspected.

In earlier times but little was known of the laws governing the action of the limes, and the rules of Vitruvius seem to have been the only guides. Recently chemistry has dispelled much of the mystery, and through the researches of Vicat, of France, followed by other engineers, has thrown sufficient light upon the chemical actions involved in the manufacture and hardening of limes and calcareous cements, to admit of the establishment of such rules for the manipulation of the ever varying ingredients of mortars and concretes, that absolute failure of an ordinary work need never occur.

Recently the rapidly extending use of cements in various ways has led to a reasonable approach to a careful system of testing, proportioning, and mixing ingredients, and of finally testing and studying the product in its stages of induration.

This article has been prepared with the hope of so presenting the subject in a brief and rudimentary form as to assist inexperienced readers of ENGINEERING NEWS to an intelligent use of the materials discussed, and also that they might realize the importance of diligent experimental study before attempting their employment in an important work. Engineering literature contains much that is easily accessible on this subject.

There is yet ample field for investigation and a profitable exercise of skill, good judgment and ingenious device in the attainment of economy in the adaptation of these materials to works of construction. Study will surely tend to multiply and increase the future applications of concrete, as it has already, within the past fifteen years, brought it to an equality with the best masonry, from which it differs only on questions of cost. The cheaper production of late of the better class of cements, keeping pace with demand for a better article, has favored their more general application.

Concrete is of very ancient origin. Its use by the Romans is attested by the ruins of their works in England. From the "slime" of the Tower of Babel to the cements of to-day, mortars have been in demand and have consisted of pulverized earthy substances, from pure clay to the best modern calcareous cements, in great variety and of all degrees of value, from worthlessness to a capability of rapidly attaining the hardness of the best building stones themselves. Many of these have formed the cementing elements of concrete.

Concrete or *beton* is an artificial mixture of mortar with pebbles, broken stone, bricks, tiles, old pottery, shells, or any substances to which mortar will firmly adhere, the strength and durability of the mixture depending, of course, upon those of its ingredients, according to the proportions in which they enter. It is really a species of masonry without artificial bond, and is sometimes called concrete masonry. The coarse, inert substances incorporated are called aggregates or ballast. Formerly the term concrete was applied only when the cementing material or matrix was such that, like common lime, it could be used in open air situations only, while *beton* which contained hydraulic mortar, was fitted for wet foundations or submarine works. In England these terms were lately, if not still, applied to distinguish methods of mixing. When all the ingredients were first mixed together dry, in proper proportions, and the water afterwards added—the lime, if used, being thus slaked in the mass—the compound was called concrete; but when the mortar was made before the admixture of ballast it was called *beton*. At the present time in this country, any compound of lime or calcareous cement mortar with ballast, by any process, is called concrete, whether hydraulic or not. Hydraulic cement is, however, almost invariably used, and pebbles, with broken stone, bricks or shells, commonly form the ballast. Bituminous and tarry concretes for walks, etc., are not included under this title in an engineering sense. When properly prepared and at once compacted, it hardens, or "sets," forming an artificial conglomerate or pudding stone.

The obviously paramount importance of the cementing element, or matrix, in concrete, entitles it to our principal consideration, and we will therefore briefly sketch the characteristics of the materials chiefly depended on for this purpose, premising that, to obtain an expert knowledge of them, much study and experimental analysis are requisite.

Formerly, and especially in England, the matrix consisted of common lime, then came the natural cements (in England called Roman), and finally the Portland cements, natural and artificial. As ordinarily found in the market at the present time, these take rank, as to strength and cost, in the order named, the prices being approximately, in the Eastern States, 30 cts., 40 cts., and one dollar per cwt., respectively. The three classes include endless varieties, making the lines of division necessarily arbitrary. Portland cement, however, is much less variable than the natural products, being entirely under the control of the manufacturer. The basis of them all is pure lime (protoxide of calcium) which, though practically useless alone for mortar, is, in combination with clay and other substances, capable of hardening or "setting."

Lime is generally found in nature as a carbonate, or limestone, occurring in great variety, of all colors, widely diffused, and containing varying proportions of several impurities, such as magnesia, silica, alumina, oxide of iron, etc. The mineralogist distinguishes the varieties as argillaceous, magnesian, ferruginous, etc., if the predominating element be clay, magnesia, or iron, respectively. Other less important substances are always found in small quantities in all limestones, and exert more or less effect on the combination. Hence no two quarries yield identically the same quality of lime.

In order to obtain ordinary quick lime, the stone is subjected to a process of calcination, or "burning" (in kilns with alternate layers of coal), which drives off the carbonic acid and water, reducing the stone about 45 per cent. in weight, and from 10 to 20 per cent. in bulk, in which state it possesses great avidity for water. This process is of the highest importance in the preparation of all limes and cements, natural or artificial, one which they must all undergo, and upon the careful and faithful conduct of which depends the homogeneity of the product and its property of setting quickly or slowly. To secure uniformity in the result, each kind of limestone must be studied separately, as also the changes of weather while burning. The difficulty of the process and diversity of results increase considerably when the amount of impurity greatly exceeds that of common lime. The finer varieties of marble, for instance, yield pure lime, while ordinary limestones, containing not more than ten per cent. of the impurities above mentioned, yield what is known as common, or fat, lime. The quality of lime varies with the increase of impurities, until the more complex varieties become the so-called cements, a generic term misapplied to the products of a particular class only of limestones.

The process of calcination as generally applied to limes and cements is fully detailed in General Gillmore's "Limes, Hydraulic Cements and Mortars," the best treatise on the subject by an American, if not by any author, and to which the present writer is much indebted.

Previous to being used in mortar the limes must undergo the process of slaking, to render them more suitable for incorporation with other substances, and to prevent a subsequent swelling in the mortar and consequent damage to the work. In old lime this may have already taken place imperfectly by contact with air, but, when properly done, the result is good slaked lime, or hydrate of lime. The more of the usual impurities the lime contains, the less its augmentation of bulk in slaking and the greater its capability of hardening under water. The latter quality confers upon it the title of hydraulic lime. The ratio of lime, to the clay and magnesia together, has been termed the *index of hydraulicity*.

By the characteristics of the products of limestones developed by slaking—the power of hardening under water, etc.,—they are classified as common lime, poor lime, hydraulic lime, and natural hydraulic cement.

Common lime, also termed *fat*, or *rich* lime, is the ordinary article of commerce—that used for brickwork, house plastering, etc.,—and contains less than 10 per cent. of impurities. In slaking it absorbs about one-third its bulk of water in passing to powder, and two and one-half to three times its bulk in taking the consistency of paste. Slaking should be performed by the method known as drowning, after carefully ascertaining by experiment the exact quantity of water needed. The quick lime should be spread in a layer, 6 or 8 inches deep, and the whole of the water thrown at once evenly over it, when considerable heat and vapor will be rapidly evolved, and the mass will swell from two to three and one-half times its original bulk. If allowed to set without a large dose of sand, this paste shrinks to such an extent as to preclude its employment as mortar. The sand aids in preserving the bulk at the expense of porosity, and takes the place of lime. The hardening of this lime is mainly a drying process with but little chemical action further than the absorption of carbonic acid from the air, producing superficially a return to its original state of carbonate. If such mortar is much exposed to water, the lime is dissolved out and only sand left. It will never harden under water, and should never be employed in works of importance. Nevertheless, this grade of lime is of much value in many ways, and, when artificially treated with other substances, furnishes compounds of the highest value as mortars. A very valuable application of it is made in the production of the celebrated Portland cement, to be described presently.

Poor limes are certainly poor in every sense of the word, for building purposes. They contain impurities generally ranging from 10 to 25 per cent., swell but little in slaking, and do not yield a homogeneous powder. In other properties they are similar to common lime, but they act with no uniformity, and are generally unsatisfactory to work with. The abundance and distribution of common lime in this country renders their employment unnecessary.

Hydraulic limes are subdivided into moderately hydraulic, hydraulic, and eminently hydraulic. They contain of the usual impurities, 10 to 20, 17 to 24, and 20 to 35 per cent. respectively; slake slowly with slight rise of temperature, evolving little or no vapor; increase in bulk not over 30 per cent.; and set under water in periods ranging from 1 to 20 days, according to their position in the scale of hydraulic energy. An abundant supply of the natural cements, possessing superior qualities, is a bar to the extensive manufacture, in this country, of the hydraulic limes, but they have been largely used in Europe. The celebrated Thiel lime of France, possesses great hydraulic value, due to about 66 per cent. of silicate of lime, and its successful employment on a large scale in constructing in sea water, for which it is considered eminently adapted, has placed it quite iat the head of the class.

Natural hydraulic cements differ from the hydraulic limes in that they contain from 30 to 60 per cent. of the impurities, retaining from 70 to 40 per cent. of lime, do not slake when mixed with water, and therefore maintain a uniform temperature and bulk throughout the processes of mixing and setting. The latter quality renders their use, in a pure state, possible and often advantageous. The color of these cements is variable, due chiefly to oxides of iron and manganese, and furnishes no guide for judging of their cementing value. In this country the common dark brown or drab color has received the general confidence of workmen, who are often prejudiced against a light colored cement until convinced by experience that there is necessarily no difference.

These cements are as diverse in proportion and variety of ingredients as the hydraulic limes, both being derived from sedimentary rocks, and hence unremitting caution must be exercised by the manufacturer in the selection as well as the calcination of the stones, requiring both honesty and a judgment begotten of large experience. Homogeneity, rapidity of setting, and ultimate strength of the product are thus greatly influenced. It is, however, common in this country to find cements that are good at all stages of calcination. Few manufacturers have carefully studied the different layers in their quarries, and it is common for them to use all the stone quarried and trust to empirical mixing to obtain desired grades of cement. The calcination in kilns similar to those for lime, is usually stopped below the point of vitrification to facilitate the subsequent process of grinding and to increase the hydraulic activity. The calcined stones are next passed through a cracker, which reduces them to pieces the size of a pea, and finally pulverized between French burr millstones. Here again it becomes necessary to the perfection of the cement that the requisite power be wisely and honestly expended, as the degree of fineness affects its strength and capacity for sand in mortar. Cements always greatly differ in this respect. To ensure very perfect chemical action in hardening, they should be reduced to an impalpable powder of which at least 92 per cent. will pass a sieve of 6400 meshes to the square inch. When ground they are at once packed in barrels, 300 lbs. to each, lined with paper to prevent loss and contact with air, and are then ready for the market.

The rapidity of setting steadily declines from the time the cement leaves the mill. It sometimes sets in three or four minutes and may occupy as many hours, but the best quality sets in from fifteen to thirty minutes. Quick setting is produced by under burning and is not an indication of ultimate strength. The activity and even the property itself of hardening may be preserved for a length of years only by total exclusion of air and moisture. Exposure to the air in the ordinary barrels favors the absorption of moisture and carbonic acid, producing carbonate and hydro-silicate of lime, etc., sufficiently to seriously lower its hydraulic activity and strength in a few months, and in time to neutralize them entirely. If, however, such ruined cements be moistened and mixed in small balls with about ten per cent. of clay and recalcined by subjection to a red heat for 1½ to 2 hours, their valuable qualities may be restored. It is not uncommon to find cements, containing an excess of free lime, that are safer to use when six months old than when freshly ground.

This general description of natural cements applies more particularly to those of this country where they have been extensively used. Until within a few years, when the artificial so-called Portland cement began to be imported, they were almost exclusively depended upon at all important works in masonry or concrete, in water or on land, large amounts being used by the government engineers. Deposits of stone, furnishing them, are found in great quantity in the United States, principally in the eastern sections, much of it of superior quality. Some of the finest stone exists and is worked in Pennsylvania and Virginia, but Ulster county, New York, is the principal source of supply, being situated near the Hudson river, in easy communication by rail or water with all parts of the sea coast and interior of the country.

The cements manufactured here are among the best of their class for works in salt water, due to a large percentage of magnesia in combination with silica and alumina. Their hydraulic induration is largely due to the partial formation, during calcination, of silicate of lime, subsequently completed by the agency of water when made into mortar.

The variations of composition to be found in the Rosendale cements is shown in the following:

Silica, clay and insoluble silicates,	11.10	to 39.74	per ct.
Alumina	2.34	to 7.50	"
Peroxide of Iron	0.76	to 5.38	"
Carbonate of Lime	28.43	to 46.00	"
" Magnesia	14.43	to 39.04	"
Chlorides of potassium and sodium,	1.68	to 7.42	"

Hydraulicity is assisted by the presence of the last named substances. These cements weigh about 70 lbs. per struck bushel. An excess of lime is detected if heat is developed, when mixed with water, but more delicately if they swell and crack while setting.

The Roman cement of England was first prepared there in 1796. Its name is said to have been derived from the resemblance of its mortar to that found in the Roman ruins. It is similar to the Rosendale of this

country, but is considered somewhat superior in hydraulic activity and final hardness, though not ground so fine.

ARTIFICIAL HYDRAULIC CEMENT.

We will confine our description of this class to that member of it which has so recently risen into deserved prominence, and which is known as Portland cement, a name probably suggested by its resemblance, in color and texture, to the Portland stone of England.

This cement was originally manufactured and introduced on a small scale in Europe rather more than fifty years ago, but lack of appreciation of its merits and probably the cost of production prevented its extensive use until within twenty years, during which time it has rapidly grown in favor and now ranks above all other calcareous cements. It is a double silicate of lime and alumina, produced by artificially assembling the proper proportions of desirable elements, to the exclusion of the injurious ones always present in the natural cement stones. While Roman cement requires only a few days for its manufacture, the Portland occupies two months or more. But little has been made in this country. Possibly the higher cost of labor, and the lack here of suitable clay and the soft and peculiarly adapted chalk of England, will continue to prevent successful competion with English makers.

The English Portland cement is composed of chalk and clay, though limestone, shell, etc., may be, and are used, more or less, as sources of lime. The process of manufacture is comparatively simple, good results being unerringly ensured by the exercise of reasonable care and watchfulness. These are first required in the selection and digging of the clay, a labor that is therefore entrusted only to the most reliable workmen kept constantly employed at it. All impurities, as sand, vegetable mould, etc., must be strictly avoided.

Analyses of ingredients are given as follows:

Fair sample of clay.		*Thames chalk.*	
Silica	68.45 per cent.	Lime	56.5 per cent.
Alumina	11.04 "	Carbonic acid	43.0 "
Carb. lime	0.75 "	Water	0.5 "
Oxide iron	14.80 "		
Alkali	4.00 "		

An analysis of a good sample of the finished cement should give calcium 62, silica 23 alumina 8, and oxide of iron 4 parts.

There are two principal processes followed at different works for the manufacture of Portland cement, distinguished as the "wet" and "dry." By the wet process, most used in England, the clay and finely-sifted chalk are mixed together in proportions of about 1 to 3 by weight, and ground with water under edge runners. It is afterwards allowed to settle for some time, when the surplus water is drained off and the mass subsequently nearly dried upon drying stoves. After being kneaded into balls about 3 inches diameter it is burnt at a high heat in an ordinary kiln to a point verging upon vitrification, and finally ground between millstones to an impalpable powder. By the dry process, which is more generally practised in Germany,—being better adapted to the working of the harder limestones,—the clay and carbonate of lime are dried and then reduced to an exceedingly fine powder by passing, as may be required, successively through a stone-breaking machine, edge runners, and horizontal mill-stones. The ingredients are mixed together in proportions varying from 20 to 23 per cent. of clay, and 80 to 77 per cent. of carbonate. The powder is wrought with water into a stiff paste and formed by machinery into bricks which are dried and then burnt at a barely vitrifying heat, by which their weight is reduced 40 to 50 per cent. The bricks are finally ground to powder as in the wet processs, the stone-breaker and other machines being again required here to effect the reduction. Success in burning depends, as with the natural cements, largely on the judgment of the burner.

Unlike the natural cements the Portland does not deteriorate by exposure to common dry air, but, on the contrary, it is better to defer packing the freshly ground cement to allow a short period of airing. It is imported in barrels about the size of those for Rosendale cement, though, from the greater specific gravity and closer packing of the Portland, they weigh one-third more, or about 400 lbs. each.

Two chief causes of the superiority of this cement are, the intimate homogeneous mixture of the chalk and clay, and the close approximation to vitrification in burning. Competition and the high quality exacted by English engineers compel the more responsible and larger manufacturers, at least, to constantly employ skilled chemists who frequently analyze the materials and preserve accurate proportions.

At Boulogne in France is found a natural deposit of soft calcareous clay containing the proper proportions for good cement, and which may be excavated with the shovel. It is probably the only similar deposit worked. The material is burned as for the Portland cement above described, yielding what is known as Boulogne Portland cement. Being strictly a natural cement it might have been so classed here. It is alleged to possess a strength slightly superior to that of Portland proper, but requires from twelve to eighteen hours to set.

The more uniformly the calcination is effected at the proper temperature throughout the mass, the greater will be the weight of the cement,—a highly desirable quality. This may vary from 90 to 140 pounds per English bushel, and the time of setting, consequently, from 10 minutes to perhaps two days. Quick setting is gained at a sacrifice of strength, while the heavier cements are more costly to produce. The English standard of quality combines three distinct tests, namely: weight, 110 lbs. per struck Imperial bushel loosely measured; fineness, sufficient to pass a sieve of 1600 to 3000 meshes per square inch; strength, 200 lbs. tensile per square inch, when seven days old, first day in damp air and balance in water.

The facts, that an increase in weight of 24 lbs. per loose bushel, say from 100 to 124 lbs.—obtained by a well managed high temperature in burning,—nearly doubles the tensile strength; that extreme fineness is a very important desideratum in all limes and cements; and that the specified tensile strength can be easily conferred with the other qualities, show the necessity for, and fairness of, such a standard. Cement of such a quality may be said to set in about three hours, although it begins to stiffen somewhat sooner; attains a reliable solidity in not less than a day or two; and becomes very hard in a week. In three months its hardness exceeds that of ordinary bricks, and in a year is equal to that of the strongest sandstone, marble, and even some of the granite. The color of Portland cement is no sign of quality, being usually greenish grey in the English and often a pale reddish tint in the German grades.

The experiments of Smeaton and Vicat, showing that good hydraulic cements harden and improve with much greater advantage under water than in the open air, have been fully confirmed. Portland cement mortar is, in fact, impaired in strength if not kept moist, or better, under water during the period of induration. Small moulds, in which such mortars are deposited, should therefore not be opened to expose the surfaces to drying air under three or four days, though the mass may have sufficiently set to maintain its form.

The volcanic products known as puzzuolana and trass formerly much employed in Europe, in combination with lime, for mortar, call for no more than a mention here. They are hardly to be found in this country, and even in Europe have been largely superseded by the modern cements. Their action is, moreover, attended with uncertainty.

(*To be continued.*)

CORRESPONDENCE.

CORRECTION.

NEW YORK, *Feb. 14th, 1877.*

Editor ENGINEERING NEWS:

SIR.—In ENGINEERING NEWS of Feb. 10th, which is remarkably full of good engineering meat, I notice a little error in your brief paragraph on page 36, referring to a report upon Rapid Transit, etc. You say the "Gilbert Elevated, etc." It is not the Gilbert, which is a different plan entirely, not yet built. It is the "New York Elevated Railroad," that is doing a large and increasing business.

Your journal ought to be getting subscribers, if they come in proportion to what you give for the money.

W. MILNOR ROBERTS.

We may note that we were corrected on the same subject by Mr. J. J. R. Croes of New York city, but his letter was mislaid before getting into type.—[ED.

OTTAWA, ONT., *Feb. 15th, 1877.*

Editor ENGINEERING NEWS:

SIR.—In your issue of 3d inst. is a letter from Mr. LeBarron, on a mode of keeping levels I would gladly see introduced on this continent.

It is the system I have always used and seen used in England; and I have endeavored in vain to introduce it here. It is the only *safe* and *scientific* way of keeping levels, for each reduced level depends on the preceding, and at every change of instrument the leveler can check the reduced heights, whereas by the mode of working from "height of instrument" there is no check at all.

In the example given in your paper there is a very good test of both English and American systems. On looking over the levels I unconsciously applied the check and found an error of 0.040, *which could not have been found by the American system.*

TABLE OF LEVELS.

Station.	Back Sight.	Intermediate	Foresight.	Rise.	Fall.	Reduced Levels.
0	7.408					284.364
1		6.57		.838		285.202
2		5.70		.870		286.072
3		5.64		.06		286.132
4		5.50		.14		286.272
5		5.52			.02	286.252
6			5.217	.303		286.555
	6.671					
7		6.13		.541		287.096
8		5.28		.85		287.946
9		5.24		.04		287.986
10		3.93		1.31		289.296
11		3.93				289.296
12		4.20			.27	289.026
13		3.28	3.28	.92		289.946
	14.079		8.497			
			Diff. 5.582		Diff. 5.582	

In the above table my rule for checking, which I apply both to every change of instrument and at the bottom of each page is simply this:

1. Add the backsights and foresights together on every page and take the difference. This should be the same as the difference between the first and last reduced level on the page. The last reading on the page is always used as a foresight. Thus:

7.408+6.671 = 14.079
5.217+3.280 = 8.497

Difference..... 5.582
Elevation at top of page.....284.364
" bottom " 289.946

Difference..... 5.582

2d. By taking the difference between the back and fore sight at each change of instrument a check is obtained, viz.:

B. S = 7.408 F. S = 5.217, difference, 2.191
Elevation, 284.364 286.555, " 2.191

From this the rule is obtained:

When foresights are subtracted from backsights there is a rise of levels: When the reverse occurs there is a fall.

There was an error in the example given by Mr. LeBarron. In the 4th foresight 5.64—5.50 = 0.100 as printed, instead of 0.140, and the error of 0.040 is carried all through the column. Had he applied my system of checking he would have discovered his error at once.

In the foregoing table I have made up the levels, according to the form used in England.

In my practice in Canada I have found several errors in Bench marks, traceable to the error of reduction from "height of instrument," which could not have occurred had the levels been reduced on the system proposed by Mr. LeBarron.

ALAN MACDOUGALL.

ROCHESTER, N. Y., *Feb. 14, 1877.*

Editor ENGINEERING NEWS:

SIR—I notice that your correspondent, Eliot C. Clarke, of Boston, in his communication of Nov. 8, 1876, calls attention to Kirkwood's modification of Prony's formula for the discharge of water through pipes or sewers. He says: "Kirkwood, for instance, modifies Prony's formula from

$$\text{Disch.} = 38.08\sqrt{\frac{D^5 H}{L}} \text{ to } 38.08\sqrt{\frac{D^4 H}{L}}$$

varying as the square root of the diameter, or in a 9-ft. sewer, as 3 to 1.

Kirkwood, in his report on the Brooklyn Water Works, gives the formula as follows: $m = 38.08\sqrt{\frac{D^5 H}{L}}$ which he changes to $D = \left\{\frac{m^2}{1450\,S}\right\}^{\frac{1}{5}}$ where m = cubic feet per second, D = diameter in feet, and S = the head divided by the length.

In his remarks on Mr. Roe's tables, he says: "Mr. Roe takes a rainfall of one inch the hour as his standard in the above table."

"The formula already given was $D = \left\{\frac{m^2}{1450\,S}\right\}^{\frac{1}{5}}$

"When this is make applicable to acres it becomes $D = \left\{\frac{m^2}{5804\,S}\right\}^{\frac{1}{5}}$, m standing for acres."

"When the last form of formula is altered to, $D = \left\{\frac{m^2}{5804\,S}\right\}^{\frac{1}{6.4}}$ it will be found to approximate very nearly to the diameters given in Mr. Roe's tables."

"To simplify the root of the formula and to insure its always giving results somewhat in excess of Mr. Roe's tables, I give it the following form: $D = \left\{\frac{m^2}{5804\,S}\right\}^{\frac{1}{6}}$ where it is desired to apply it to the areas in acres—and where it is desired to apply it to the cubic of discharge at any point, governed in that case by the length of streets delivering to that point as heretofore explained, the formula becomes $D = \left\{\frac{m^2}{1450\,S}\right\}^{\frac{1}{6}}$ "

I fail to perceive how the length of the street affects the diameter of the pipe as long as m remains the same. If m = 10, for instance, the diameter must be sufficient to carry 10 cubic feet per second without regard to the length of street it has passed over to arrive at the sewer.

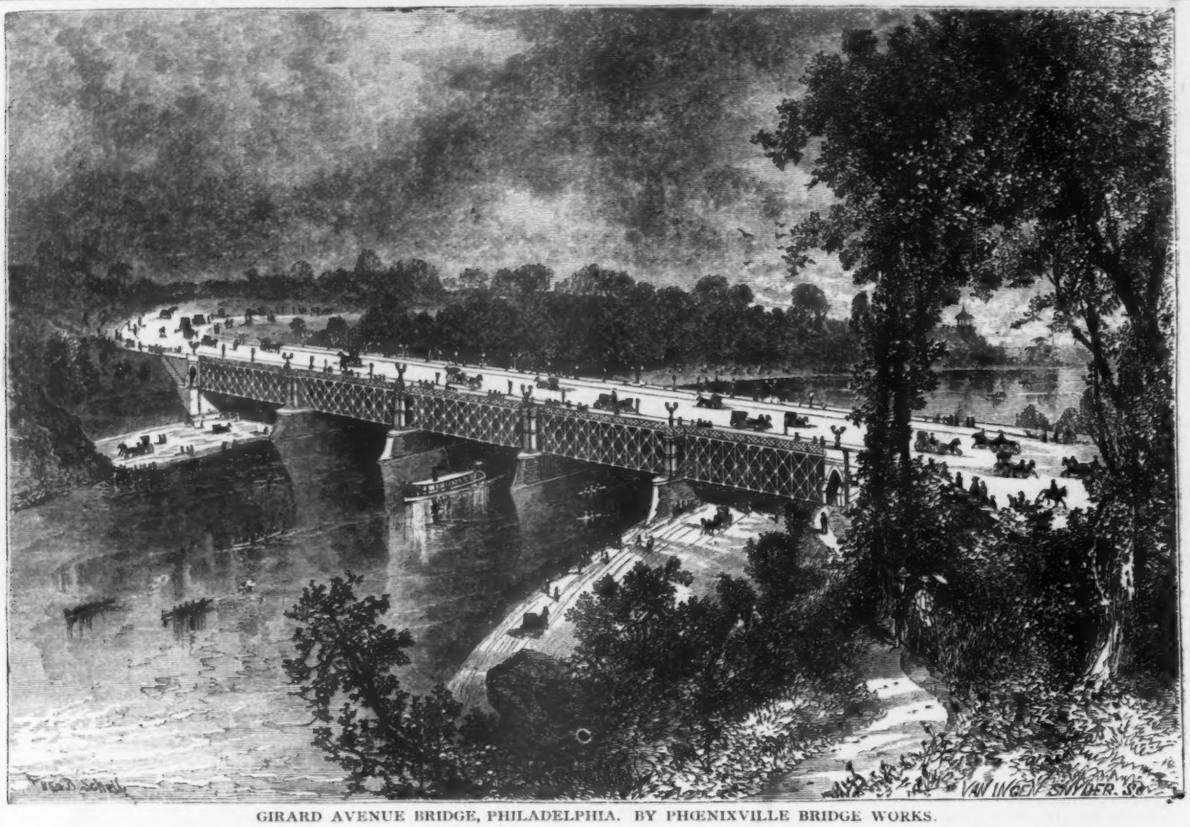
Mr. Kirkwood quotes a formula from Bazalgette for determining the diameter of a sewer sufficient to carry off one inch of rain per hour per acre.

One inch of rain per hour per acre = 1.00833 cubic feet per second per acre.

In applying his formula to Mr. Roe's tables. Mr. Kirkwood, by his modified formula makes a pipe 26 inches diameter with a grade of 1 in 240 sufficient to drain 50 acres, which, according to the explanations = 50.41 cubic ft. per second. Now Prony's formula, which he modifies, would make the capacity of that pipe 8.56 cubic feet per second.

Mr. Kirkwood has substituted n for m in his formula, and then modified it to conform to Mr. Roe's tables of actual experiments, and then has applied the same modification to the original formula, which is erroneous; because m refers to a definite quantity in a definite time, but n refers to a definite number of acres, but a varying time, because the greater the area drained, the greater distance must the water travel to arrive at the sewer, and therefore a greater time.

The distances which the water has to travel to reach the sewer will vary as the square root of the area drained, and the time of its passage to the sewer will



GIRARD AVENUE BRIDGE, PHILADELPHIA. BY PHŒNIXVILLE BRIDGE WORKS.

vary in the same ratio, so that Mr. Kirkwood's modification of the formula with n as a factor is right and proper, but is not right when it contains m as a factor.

I therefore conclude that the formula $D = \left\{\frac{m^3}{1450\ S}\right\}^{\frac{1}{6}}$ is erroneous.

L. L. NICHOLS.

SPECIFICATIONS FOR THE IMPROVEMENT OF RAPPAHANNOCK RIVER, VA.

1. *Locality.*—The location of the work is on the Rappahannock River, at Fredericksburg, Virginia.

2. *Dredging.*—A channel nine feet deep at low water and fifty or more feet in width, is to be excavated through portions of Fredericksburg Bar between Deep Run and the railroad bridge. The material to be excavated is sand. The depth of cutting varies from two to four feet.

3. *Deposit.*—The excavated material will be deposited behind the several dikes, or on the banks of the river, at a varying distance from the work of from thirty to five hundred yards. For a small portion of the dredging (about 2,500 cubic yards) this distance may be seven hundred yards. Light-draft shoveling scows will be required for this purpose. They must be provided with sides, which shall always be used. The scows can be poled by hand and the dikes reached at all stages of the tide. The material will be deposited at an average distance of one hundred feet behind the face of the dikes (for which work an ordinary scraper may be used) and must be leveled off at such height as the Engineer may designate.

4. *Depth.*—The depth of the channel when completed shall not be less than nine nor more than ten feet at low water. If less than nine feet is found the channel must be re-excavated until that depth is obtained. Excavation below ten feet will not be paid for.

5. *Construction of Dike.*—A dike is to be built on the right bank of the river, below the steamboat wharf, in the following manner:

A. *Dredging.*—The line of the dike is to be dredged to a width of five and a depth of eight feet at low water, where required.

B. *Piles.*—Along the line designated for the face of the dike oak piles twenty-two feet in length and one foot in average diameter are to be driven, ten feet apart from center to center. Parallel with and ten feet in the rear of the front row, a second row is to be driven, the piles to be also ten feet apart from center to center, and to stand at right angles to the corresponding piles on the front row. The piles in the rear row are to be of oak twenty feet long and one foot in average diameter. A fender pile of the dimensions specified for the front row is to be driven at the middle of each bay. All the piles are to be of live timber, sound and straight, and are to be sharpened and well and carefully driven so as to stand plumb and true to the line. Each pile shall be driven so that it has its full length below the level of the top of the dike, which is six feet above low water; the top of the pile shall be cut off at this level. The contractor will be required to band the tops of the piles during driving, if found necessary.

C. *Wale pieces.*—After the piles have been suitably notched to receive the same, two wale pieces are to be bolted along the inside of the front row of piles. The upper wale is to be of pine timber, 6 inches by 12 inches, in lengths of at least twenty-one feet, set so that the upper edge shall be four and a half feet above low water. The joints are to be halved and to come on the piles. The wale is to be bolted to each pile with a 1-inch iron bolt, with nut and washers, and 20 inches long, and to be spiked thereto with two 10-inch ship-spikes (9-16ths inch square) of wrought iron. The lower wale is to be of pine timber, 4 inches by 8 inches, in twenty-one feet lengths, set so that the upper edge is at low-water mark. The joints are to be halved and to come on the piles, and the wale is to be spiked to each pile by two wrought iron ship-spikes 9 inches long and 9-16ths inch square. The two wale pieces will break joint, and the inside faces must be in the same vertical line.

D. *Sheet piling.*—The sheet piling is to be of three-inch heart-pine plank eighteen feet long. The piles are to be sharpened and carefully driven along the inside of the wale pieces, and the tops neatly sawed off at the level of the top of the dike, the piles to be of the required length below this level. Every other pile is to be driven against the wale pieces, and the intervening piles are to be driven behind these so as to lap three inches on each edge and form a close joint. Each sheet pile is to be spiked to each wale or to each adjacent sheet pile with two wrought iron spikes 6 inches long and 3-8 inch square, four spikes being used in each sheet pile.

E. *Ties.*—After the sheet piling has been driven, the corresponding front and rear piles are to be connected by tie pieces of pine timber, 6 inches by 12 inches, in lengths of twelve feet, with square ends, bolted to each pile with two 1¼-inch wrought iron bolts 20 inches long, with nuts and washers. The piles and sheet piles are to be suitably notched to receive the ties.

F. *Material, etc.*—All the timber for sheet piles, wale pieces, and ties is to be of the best heart-pine lumber, free from wind, shakes, or any other defects. The iron for the bolts is to be of the best quality of wrought iron. Holes of the proper size are to be bored for each bolt, and for large spikes when required. All the material and work is to be satisfactory to the Engineer or Inspector, and such as does not fully conform with these specifications will be rejected. Moreover the dike when completed shall conform to the plan of the same in the office. The dike will be estimated by the lineal foot.

6. *Quantities.*—The estimated amount of excavation is 20,000 cubic yards; of dike 350 lineal feet, more or less. These amounts are approximate, and may be increased or diminished as the funds require.

7. *Tides.*—The mean range of tides is three feet. The locality is entirely sheltered.

8. *Machinery.*—All machinery must be adapted to the work and kept in good order. The scows must be sound and tight.

9. *Inspector.*—An Inspector will be appointed by the Engineer, who will act as his agent in the immediate charge of the work. In accordance with the instructions of the Engineer, he will indicate the special locality of dredging and deposit, and supervise the construction of the dike, and will enforce strict compliance with the contract and specifications.

10. *Measurement.*—The excavated material will be measured in scows by cubic contents. The Engineer shall determine the capacity of each scow, and the Inspector will determine when the scows contain full loads, and keep a record of the same.

11. *Lines, etc.*—The precise location of the work will be fixed by the Engineer in charge. The exterior lines of the channel will be plainly marked by stakes or ranges, and no dredging done outside these limits will be paid for. Intermediate ranges, if desired, must be set by the contractor. The Inspector will set tide-gauges at convenient intervals, and the contractor will be held responsible for any loss or delay arising from injury to stakes or gauges by his own employes. The contractor will be required to supply lumber for stakes to mark the direction of the channel, and also furnish labor for setting the same, and for the necessary examinations and soundings, under the direction of the Engineer in charge—the expense of the same to be included in the price of dredging.

WE present this week an illustration of the Girard Avenue Bridge, Philadelphia, erected by the Phœnixville Bridge Works. This is also one of the plates serving to make the work on Iron Highway Bridges, by A. P. BOLLER, C. E., at once as attractive as it is useful and instructive.

AT the annual meeting of the American Microscopical Society of the city of New York, held Tuesday evening, January 9th, 1877, the following officers were elected for the ensuing year: *President, John B. Rich, M. D., 1 West 38th street, New York; *Vice President, Wm. H. Atkinson, M. D., 41 East 9th street, New York; Secretary, O. G. Mason, Bellevue Hospital, New York; *Treasurer, T. d'Oremieulx, 7 Winthrop Place, New York; Curator, John Frey, Bellevue Hospital, New York.

*Re-elected. O. G. MASON, *Secretary.*

ON Monday night last, the 19th inst., a fire, originating in the frame buildings over which the great St. Louis bridge passes, at its eastern approach, seriously damaged some 300 feet of the structure itself—according to the latest advices. The *St. Louis Globe Democrat* of the 20th, after referring to the usual hitch in the water supply says: "The rookeries took fire and so did the bridge, and the latter, the pride of St. Louis, is impassable and likely to remain so for some time, by reason of a gap of some 900 or 1,000 feet in the eastern approach. All that remains of this portion through which the fire passed, are the braces and uprights, every particle of combustible material having been burned away." Loss on the bridge at the lowest possible figure is estimated at $125,000.

MANUAL EDUCATION BY SCHOOL SHOPS.

The subject of technical education, especially as pertaining to the thorough instruction of young men in the mechanical trades, seems to be very generally engrossing public attention. The endeavor of the Massachusetts Institute of Technology to establish instruction shops, where not only the students already pursuing scientific and engineering studies in the professional classes shall be taught all the elements of workshop manipulation in iron and steel, but also special students, desirous of acquiring a trade shall be trained systematically, so as to acquire in the shortest time that dexterity in the use of tools which characterizes the master workman, has been noticed approvingly by the press. Unfortunately another project, set on foot by Mr. Ruggles, endorsed by Wendell Philips and Professor Watson, formerly an instructor at the Institute, and advocated before the Social Science Association and through the papers, has seemed to conflict with the first, and, as both schemes are urged before the Massachusetts Legislature, with the petition for a grant of public aid to equip, and support for the present, the desired shops, a collision between the two has been brought about which otherwise seems unnecessary.

The course of instruction at the Massachusetts Institute of Technology is modelled upon that of the Imperial Technical School of Moscow, a description of which we gave at some length in Vol. III., No. 47, for November 18, 1876, and we would refer to that article for a detailed description. In the preceding number, of November 11, we gave our opinion of the utility of industrial schools as compared with the now, we may say, almost obsolete system of apprenticeship, and we will not therefore repeat here our favorable endorsement of the former. The distinction drawn by President Rumkle of the Institute between *instruction* and *construction* shops is, in our opinion, well made. In the first case the shops initiated at the Institute, the pupil is set to work on a task which embodies some principle in its simplest form, such, for example, as filing a piece of cast-iron accurately to a straight line and plane surface. When this operation is successfully performed he is advanced to another. In this way he rapidly progresses, so that he can soon shape with the file any desired and possible surface or form. There is then no need of further instruction in that work, and he is set at tasks which call for the use of other tools. Metal working, forging, pattern-making, moulding and fitting are all intended to be pursued, under the eye of an expert in each branch.

It is objected by some that the students are put to work on *junk*, and that it is junk when they get through with it. In other words, such persons want the young men to *make something*. It appears to us that a workman can learn more quickly to handle a tool so as to produce a required result when there is but one thing to take his attention, than when there are several operations to be carried out successively, on the same piece, in order to complete a finished, merchantable product. We doubt whether the students of the Mechanical Engineering Department of Cornell University were any less proud of the *true planes* which they exhibited at Philadelphia, and which any machinist could appreciate, than they were of their lathe or engine.

Then Professor Watson takes a ground of opposition to the Russian plan, or to the Institute plan, that the students are required to perform work with hand-tools that could be better done by existing machines. This has always appeared to us a very curious objection. We have no doubt that the Professor could make a truer surface on a piece of cast-iron in a planer than with a file in a vise, but that is no argument that he had not better learn to handle a file and to file true, if he were to desire to become a machinist. All machine tools have to be fashioned by the aid of other tools, and the formation of dies, gauges, templates, drills, and an endless variety of the implements used in the shop, requires hand labor. Why is it that the die-sinker or the fitter-up, the model-maker and men of this class can command high wages? Because men who have trained eyes and hands are scarce in machine shops. There are an abundance of young men who can tend a lathe or planer, run a machine-drill or a screw-cutter, but very few comparatively who are competent to get up the original patterns, designs and tools for the work in hand. We have worked in a machine shop long enough to understand the difference between tending a machine and working by hand. It may cost $400 or $500 to make an accurate working model of a breech-loading rifle, for instance, and several months to get up the dies, tools, and gauges for the manufacture, with the employment on such work of only first class workmen, but when the manufacture is once under way, the guns are turned out by thousands, at a cost of from perhaps $12 to $15 apiece, by men who get often no more than $2.00 a day. If we cannot get our master workmen to make a beginning, who will lay out the work for the common run of hands?

If a shop is to turn out finished work and to be self-supporting, the students must be kept more or less at routine tasks, carrying numbers of the same piece through one operation, which they can do as well when they have performed it two or three times as when they have turned off parts by the score or hundred. How students can be rapidly advanced, according to proficiency, in a shop where construction is the object we fail to see.

As the *file* was spoken of at some of the public meetings in a contemptuous manner, as being an obsolete instrument, it may be worth while to read the statement of one competent to judge, after an inspection of some of the students' work:

Mr. H. P. Langley, a mechanic of thirty-five years standing, after examination of a specimen of fitting made wholly by the file, stated that such skill was to him marvellous, and he believed it would be hard to find a mechanic after two years' work in the machine shops who could do such work as these lads have done in a week. He also stated that it was absurd to say to any one acquainted with mechanical operations that the use of the file was obsolete; it is in many respects the best and the only instrument that can be economically employed, and it always will be.

However, the proposition of Mr. Ruggles really has a different scope, and is independent of the Institute plan. An abstract of what is designed to be accomplished is as follows, taken from a committee report to the American Social Science Association, published in the Boston *Post*:

DEVELOPING SCHOOLS AND SCHOOL SHOPS.

The importance and the value of a practical training in the education is first emphasized, after which the Committee say that the laborer must now receive a different practical education from what was required two generations ago. Apprenticeship having departed, never to return in its ancient form, something else must take its place and give to our artizans practical instruction. By the old apprentice system the boy was bound to the master some seven years, and received his instruction more by his own observation than by any direct teaching. We recommend the plan suggested by Mr. S. P. Ruggles, and so universally endorsed by the press, in contradistinction to the former system of our fathers—that the youth, whenever he has completed his general education in any of our public or private schools, may enter what may be called a developing school, so established and arranged as to give all the pupils a good general idea of all the different trades, arts or callings, in order that it may be ascertained by themselves for the Superintendent for what kind of business they have the greatest natural genius. Imagine, if you please, one very large room with a steam-engine and boiler in the middle of it, so that all pupils that have any taste for the management of steam or steam engines, could examine every point, and readily understand all about it. Then we would have a carpenter's bench, with a variety of tools, to show how that work was done; then perhaps turning lathes, to show how the wood-turning business was performed; then with the aid of blackboards and carving tools, it might be seen how drawing and carving is done by those that have any inclination for that business. We should also have planing machines, lathes, upright drills, jig-saws, etc., to represent the machinist business. Foundry work should be shown by having the usual fixtures for sand, and two and three part flasks for moulding, etc.; the casting could be done in soft metals, as lead, zinc, or tin, which could be reused, as the whole art in foundry work consists in the different manner of moulding, and almost all other trades or methods of doing work could be pretty well represented in the same room. As soon as it should be ascertained what kind of business the pupil is best fitted for by nature, he would be recommended to the school shop where that trade should be taught, and be more thoroughly instructed in two years, and become a better mechanic, than in six or seven years under the old system of learning a trade.

After showing the difference between the mechanical shops of all kinds that should be established to teach a trade, art, or calling, and the shops already established for doing work of that particular kind, for profit, the Committee say there should be a very particular selection of the kinds of work to be made at the school-shops, consisting of lathes and planers and other tools that are always kept on sale, large and small work of different kinds, making as great variety of work as possible for the pupil to practice on.

In the school shop the pupil would advance from a lower degree of instruction to a higher as rapidly as his thorough knowledge and good workmanship would justify. The instructor would be paid a satisfactory salary, and not be permitted to make merchandise of the time of the student. All machinery or articles made by the students could be put on sale or be sold at auction, and the proceeds appropriated towards defraying the expenses of the school shops.

After commenting on the importance of changing the system of mechanical education in shops, and dwelling on the advantages of divisions of labor, which make men specialists, the Committee say: "We have planing mills, where boards are planed by the wonderful "planing machine" to an equal thickness; tongued, grooved and jointed if desired; also, machines run by steam for sticking out mouldings of every size and description. There are special establishments for making blinds, sashes and doors of every description and variety. Stair building, formerly a part of the carpenter's trade, is now a specialty or business by itself. Great changes have taken place in the machine business, caused by the subdivision of labor and the introduction of various machines to perform the labor formerly done by hand. Instead of chipping and filing to make a straight edge or level surface, the material is now placed upon the planer for planing iron, where the edge is made perfectly straight, or the surface perfectly level, in one-fourth the time formerly required before the introduction of the planing machine. This is true of other varieties of work, by means of upright drills, jig-saws, screw-cutting apparatus, polishing and emery wheels, universal chucks and other appliances to the lathe, together with other apparatus which facilities the manufacture of the various parts of the work. It is well known there is no place at the present, nor has there been for some time past, where a boy could "learn a trade."

We are pleased to learn, say the Committee that we have the hearty approval and co-operation of Mr. John D. Philbrick, the experienced Superintendent of the Public Schools of Boston, in relation to the above-proposed plan. In order to prevent misapprehension by those who have desired information in relation to the many articles published upon this subject in our public papers during the past year, we would wish to be distinctly understood that it is the object of the above plan to give to all the youth leaving our public or private schools the opportunity of obtaining a perfect knowledge of his chosen trade or occupation in the shortest possible time. Every boy, rich or poor, is, we think, as much entitled to have a good trade as to have an education in our public schools. We also believe the proposed plan would be self-supporting in a short time after being once put in successful operation. The Committee recapitulate their report thus:—

First, there would be a great advantage gained by selecting the right youth (by the developing school) for the right business; second, the boys would be taught the trade instead of getting their knowledge by observation, as was the case formerly, as it would be the whole object of the master to teach the boys, instead of making profit on their work; third, the school shop should be much more perfectly fitted up (as described) to teach the business than any shop now in operation to do work for profit; fourth, the worth of the work made by the boys would probably pay current expenses after a very short time.

THE DETROIT TUNNEL.

THE projected methods for tunneling the Detroit river increase wonderfully in number under the stimulus of an invitation from the committee to submit plans. We have lately alluded to several which have been offered, and, since our last writing, have heard of a number more. Gen. Smith's plan has been examined by the committee appointed by the Mayor of Detroit, and has been pronounced feasible. Mr. D. Farrand Henry presented plans made in 1874, when this subject was before discussed. Mr. William Scott and Mr. Henry Collins both propose tunnels, in different locations, the former putting the cost at $2,500,000, and the time two years, and the latter making his figures $2,268,000, at which sum he offers to contract to excavate it. Mr. Hall, of Mt. Clemens, proposes to sink a boiler plate tube, coated with tar and gravel to make it impervious to water. Mr. H. M. Cargill, of Grand Rapids, proposes to bore a tunnel with an earth auger, with appliances for removing boulders and other obstructions, working his machinery by compressed air. He estimates the cost at $2,500,000. Mr. McWilliams, whose scheme we alluded to on February 10, reckons the expense ot $150 per lineal foot, the tunnel to be 22 feet in diameter. Oliver Drouillard desires to sink iron tubes weighted with masonry on either side, at an estimated cost of about $200,000. Then there is a plan for an underground hydraulic tunnel, though what that is we fail to guess. Still another ingenious inventor proposes to solve the difficulty by quite another method, that is to bridge to and from Belle Isle, and to build a canal through the island for the benefit of vessels. Mr. Lu-

ther Beecher thinks that he can tunnel underground for $100 per foot.

Mr. John Burt, the chairman of the committee, proposes to start directly from the Michigan Central Railroad depot, thence to curve to the foot of Woodward avenue, and thence to cross the river directly, making a length of 5,280 feet. This plan contemplates the construction of a double-track tunnel, in caissons from 100 to 200 feet in length, across the entire bed of the river, the tunnel to be made of brick, in a timber caisson, with temporary bulkheads, floated out, manœuvered by tugs and sunk in line by means of guide timbers attached to the caissons already down. When bottom is reached, access is to be had to the caisson by iron shafts, the water is to be forced out by compressed air, or to be pumped out in case the caisson has taken the bottom sufficiently to exclude the water, and then excavation is to be carried on beneath until the caisson with its included tunnel is lowered to the required depth in the trench. He proposes to run hydraulic cement into a cavity left in the brick-work at the joint in order to make this portion tight. Then, finally, Mr. Coats, of Kalamazoo, has come forward with a scheme of which we have learned no particulars.

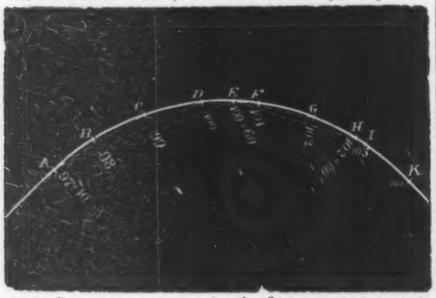
But enough of these projects, some of which are more curious than practicable; we will only say that Mr. Chesbrough has again given his opinion to the committee that a tunnel can be constructed for $3,000,000, leaving out of consideration the value of real estate which might be taken for approaches. As to the pecuniary prospects, they are favorable to the venture. New York capitalists have signified that at least $2,000,000 can be obtained on tunnel bonds at 6 per cent. interest, if guaranteed by the city of Detroit. It seems to be the general opinion that Detroit can well afford to devote $500,000 to the project. Mr. Joy stated that he would be willing to promise that the railroad companies would agree to use a tunnel, provided one was constructed, and to pay annually $200,000 in tolls. Steps for organization of a company have already been taken, and we hope that, upon the definite report of the committee, the matter will be vigorously entered upon.

METHOD OF KEEPING NOTES OF RAILROAD CURVES.

Written for "Engineering News."

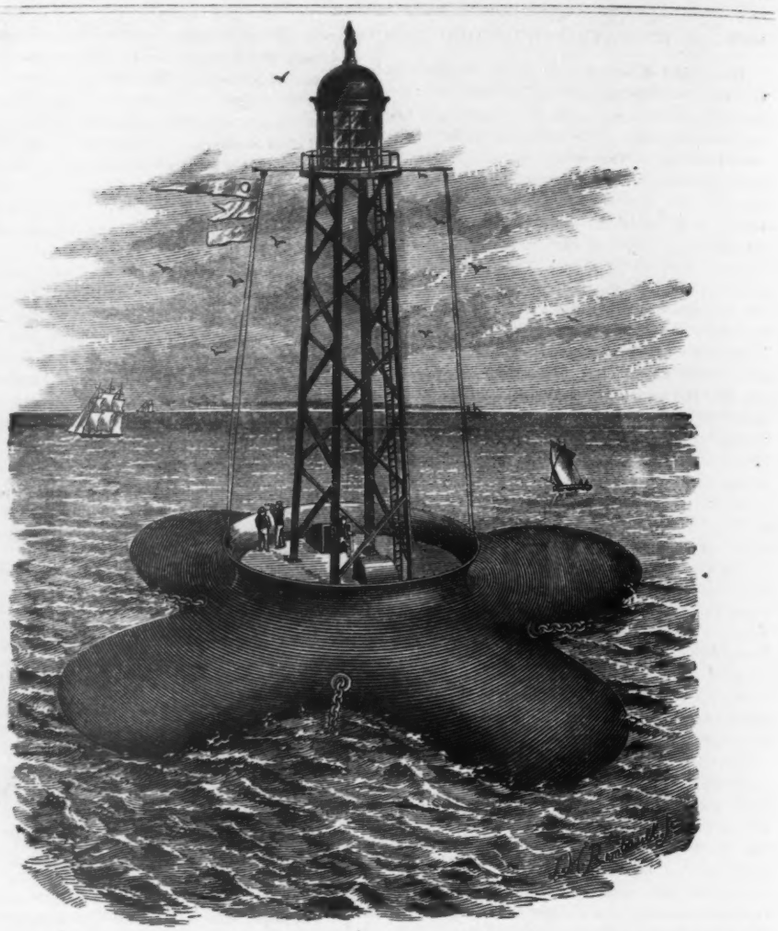
We offer, for the approval of railroad and other engineers, the following method of setting off the angles and keeping the notes for any curve, believing that it will commend itself by its simplicity and convenience for general application.

Having arrived at A on a tangent we propose to set out a curve to the right of say 2° 40′ curvature. With the instrument at A we turn off as usual the deflection angles till we locate the point E, to which the transit is to be carried forward. If A is, as marked, station 97+10, the deflection for 98 will be 1° 12′, for 99, 2° 32′, for



100, 3° 52′, for 100 + 60, 4° 40′. It now the transit is placed at E, one generally, having set the plates at 0°, sights at A, reverses the telescope and turns off 4° 40′ + 32′ or 5° 12′ for F, then 6° 32′ for 102 and 7° 36′ for 102 + 80; when the instrument is again moved to H, we should turn off the number of degrees from E to H plus the 16′ necessary to strike I.

But suppose that, before sighting at E, we set the plate at the original reading for E, or 4° 40′; then we may turn off 7° 36′ + 16′ or 7° 52′ to put in I, and can then advance as usual, adding 1° 20′ for each one hundred feet. The advantage is that each station may have its deflection worked out at once in a regular series, starting from the beginning of the curve, and the figuring in the note book may be done before the curve is run at all, as soon as the tangent point is located,



leaving only the routine to be observed that *when you sight at any point the plate must be set at the reading for that point* in the note book. Then, whenever it is necessary to put in a plus station, the number and reading will be simply interpolated in the proper columns. If one is obliged to skip any station and put it in later from another portion of the curve, to back in a portion or to re-run it, the notes require no alteration whatever. The notes are below.

Sta.		Reading
E. C.	104	9° 12′
	103	7° 52′
P.	102 + 80	7° 36′
	102	6° 32′
	101	5° 12′
P.	100 + 60	4° 40′
	100	3° 52′
	99	2° 32′
	98	1° 12′
B. C.	97 + 10	0

It will be seen that the readings run regularly and smoothly on, increasing by 4° every 300 feet.

As an illustration, suppose that we desire to set up at G, sight at E and put in the stake at C; the reading at E, station 100 + 60 is 4° 40′; clamping the plate there, sight E, turn the plate to 2° 32′ for station 99 and we shall cover C. To get on to a tangent at any point, after the plate is set for, and the telescope sighted at any point, simply set the plate for the reading which belongs to the station at which the instrument stands. The telescope need never be reversed, but can be turned on the vertical axis until the vernier reads the desired angle, thus eliminating any error of collimation. The simplicity of the computations and notes, if the rule above italicized is observed, is our reason for preferring this method.

FLOATING LIGHT-HOUSES.

It is now nearly twelve years since Mr. John Moody an English sea captain took out letters patent for a vessel that was to be used for the purposes of "Floating Electric Telegraph stations and Light-ships for mid-ocean and the English and other channels." The vessel shown in the annexed engraving, excited considerable attention at the time, and the merits of the invention were presented to the English people by the public press and by the personal labors of Capt. Moody, from whose address before the Inventors' Institute in London we propose to quote quite literally. Patents were taken out in this country through the agency of Munn and Scott, and by them described in the *Scientific American*. Otherwise we are not aware of the publication of anything in this country respecting this novel structure. Capt. Moody retired from ocean service to give his entire time and energies to the perfection and introduction of his invention, but died before seeing any realization of his hopes. The labor of bringing the matter before the several governments, who might be supposed to be interested in such a project has since devolved upon Mr. J. M. Emerson, now a resident of Chicago, by whom a model and drawings of the vessel were exhibited and explained at the last meeting of the Civil Engineers' Club of the Northwest, and from whom we have obtained the particulars, and the use of the plates, for the present article. Capt. Moody in his address says:

"Assuming then, that my form of vessel is adapted for floating mid-ocean telegraph stations—which I hope to prove before I close this paper—and taking as an example an Atlantic cable, I would suggest that such a cable should be carried in short lengths by means of my floating telegraph vessels, constructed expressly for the purpose. The first of these vessels I would place somewhere in mid-channel with a cable from the Land's End. The next vessel I would place off the Western Islands, and would place a third off the Coast of America, from which I would carry the cable direct to New York.

By this means the length of the entire cable would not be increased, whilst it would be divided into several short lengths, giving the following general advantages:—

1. The diameter and weight of the cable would be considerably lessened, thereby diminishing the cost of the cable.

2. These shorter lengths could be carried out and laid by a smaller steamer than that employed in laying the present cables, thus very considerably reducing the cost of laying the cable.

3. These shorter cables, should they break, could be repaired or replaced with a new length in a much shorter time, with much less labor, and at a greatly diminished risk and cost than in the case of a cable stretching from shore to shore.

Now even supposing that the cable laid in lengths was only intended to be used at its shore ends for through messages, such a plan would undoubtedly possess the three last mentioned advantages; but when it is considered that these floating stations can be utilized for the various purposes I shall hope to develope before I close this paper, the use of such stations is at once apparent.

Among these latter advantages are the following, to which I beg to call particular attention:—

Ships could call, and masters could communicate with their owners, whether in England, France, or the Continent, on this side the cable, or in America on that side. Masters on a trading voyage, and a long time out, would thus be enabled to send home letters and papers giving full information of the results of their voyages. For it is no idle assertion to make when I say that these mid-ocean stations could be made available for post-

offices as well as telegraph stations. Arrangements could be made with the mail steamers to call for letters and anything else that might be left at the stations.

By means of these stations, money and bills could be transmitted from masters to owners.

Large quantities of all kinds of stores and provisions could also be kept there for sale to passing ships and to relieve shipwrecked people who might be picked up, or who in open boats had succeeded in gaining the station.

News of wrecks or disasters at sea, could be sent through the cable, and assistance might be obtained for many a ship which otherwise would be lost. Life-boats should be kept at these stations (built upon the same principle as the telegraph ships, somewhat modified, that is, with four rays or arms, which would render them free from liability to upset), for the purpose of saving life, rendering salvage services, and as a means of communicating with passing ships; so that all these floating stations would thus become not only places of business, but places of refuge in the very midst of the ocean. These stations could be boarded in all weather, for from their peculiar form they could always be approached on the lee side, where the sea would be much broken, and perfect safety in boarding secured.

In fact these stations might be made the centres of communication between all nations by a simple system of cross cables; as, for example, in a cable between here and America, the first or mid channel station might have short cross cables to England and France, the next station placed off the Western Islands, could have a short cable carried to the principle island in the group, putting it in communication with America, England, France, and the whole Continent of Europe; and what could be done in that case in that ocean, could be done in all other cases, and in all other oceans and seas, until the whole world became connected together.

ACCOUNT OF AN EXPERIMENT ON A CONCRETE ARCH.

Abridged from "Der Civil Ingenieur."

[FOR ENGINEERING NEWS.]

The following described experiment was made by Prof. Clericetti, of Milan, in 1871. The arch was built by a cement manufacturing company for the exhibition of that year, of which it was one of the notable sights. The dimensions were as follows:

	Meters.	*Feet.*
Span	8.08	26.51
Rise of Intrados	1.95	6.40
Depth of crown	0.095	0.31
Length of skewback joint	0.28	0.92
Width of abutments	2.00	6.56
Clear height of abutments, to springing of arch	0.65	2.07
Breadth from face to face	0.50	1.64

The arch was constructed of cement (from Val Seriana, manufactured in the same way as Portland cement) gravel and sand. At the close of the exhibition, it was given to the Royal Institute of Milan, at the request of Prof. Clericetti, to be experimented upon; the cost of the experiment was also borne by the cement company.

The experimenter had wished to submit the arch to the conditions of a highway or railroad bridge, by a horizontal permanent load; and then to test it by rolling loads. Such, however, were forbidden, as well by their cost as by the time they would consume, the arch being erected in a public place.

The test consisted in loading the arch gradually with common brick, laid without mortar, until breaking occurred. A solid wooden scaffolding was erected beneath it, and this with the arch, was enclosed by plank walls to protect passers by. In order to observe at each moment the movement of the crown, an iron plate, moving between guides, was suspended therefrom by a wire, so as to follow this movement. The arch was divided by vertical lines a half meter apart, so that the points of ruptare might be quickly and easily located.

The bricks used for the test weighed 228.5 kilogs. (503.7 lbs.) per hundred, and one cubic meter contained 680 bricks. One cubic foot, therefore, weighed 97 lbs.

After the curve of the intrados had been measured, Nov. 17th, the loading was commenced by a load over the abutments and the extrados of the arch, of four courses of bricks. These first courses formed an arch of themselves, which was afterwards destroyed by making a hole through them 5 c. m. (= 2 ins.) wide. *a* Fig. 1; this was afterwards increased as the arch compressed more and more.

Nov. 29th, the load at the crown had reached 58 courses, or a height of 2m.9 (=9.51 feet). It became necessary to interrupt the loading twice this day, for the purpose of lowering the scaffolding, which was a difficult operation. The crown had lowered at this time 18m.m. (=.059 ft.) The next morning it was found that the arch had sprung and snapped the wire suspending the plate, owing to the swelling of the guides by the rain. The platform was lowered again and an additional load of five courses placed on the arch. The curve of the arch being now measured as exactly as possible, it was found to have lowered about 5 c.m. (= .164 ft.), mainly during the night. Immediately after this, the first trace of rupture was observed as follows:

1st. A crack, exactly at the crown, in a nearly vertical position, which opened a little at the intrados and extended into the arch 3 c.m.(= .098 ft.) This crack extended only 10 c.m.(= .328 ft.) from the front face, and was not visible on the other face. This was a result, probably, of a distortion of the arch caused by unequal drying, which threw the faces out of vertical planes. This distortion was noticed before the commencement of the test.

2d. A crack in the opposite direction, viz., from the extrados inwards, near the left abutment (see Fig. 1), midway between the division lines 3.5 and 4. This crack about 7 c.m. (= .23 ft.) long curved upwards, and could be traced on the extrados from one face to the other, but upon the rear face was hardly visible.

3d. The first indications of a crack, in the neighborhood of the right abutment, at the division line 3.5.

The arch thus showed a tendency to rupture at three points by tension. The loading was continued until

92 courses had been placed, on Dec. 2d, when a photograph of the arch was made. When the loading had reached 107 courses, corresponding to a height of 5 m 4 (= 17.72 ft.), the following was noticed:

1st. That the crack at the crown had increased, so that the unsevered part was only 5c.m. (= .164 ft.), and was the same from face to face.

2d. That the crack near the left abutment had still extended itself in a curved, unsymmetrical line (see Fig.), and that the unsevered part of the arch was reduced to a third of the normal depth of the arch.

3d. That the crack near the right abutment had extended and curved upwards, as in the other half, and that the unbroken part was reduced to a third of the normal joint. It was not possible to measure exactly the extent of the crack, as the opening at the extrados was only a few thousandths wide, and the end of the crack could not be located very nearly.

A few hours after these observations were made, the arch fell during the night of December 2d. The next morning the arch, its loading and scaffolding were found a heap of broken bricks and snapped timbers, from which nothing could be learned except that the distortion previously noticed was not without influence on the fall; part of the arch having fallen vertically, while part was thrown out of line, over the scaffolding, which must have been then standing.

REUBEN SHIRREFFS, C. E.

SOUTH FRAMINGHAM, Mass.

CORRESPONDENCE.

CHICAGO, ILL., *Feb. 22, 1877.*

Editor ENGINEERING NEWS:

SIR:—G. W. P., of Kansas City, asks for information about the economy of heat in the steam engine, and then makes the statement that the gases of combustion leave a boiler with an absolute pressure of 65 or 70 pounds per square inch. This is a remarkable statement; for if there were any such pressure as this, it would run an engine without any steam being required. As blast furnaces carry only from four to five pounds pressure to the square inch, it is of no use to say anything more about his 65 or 70 pounds.

With regard to the heat of the escaping gases, he is nearer the right thing, but is somewhat too low in his statement; for, with the heat of the steam in the boiler at 300° it follows that the gases entering the chimney must be hotter, the variation depending upon how hard the fires have to be worked to keep up the supply of steam, and the harder the fires are worked, the hotter will be the escaping gases.

Then he says: "Suppose that steam at a temperature of 300° is admitted to the smaller cylinder of a compound engine, and then is expanded to a temperature of 200° in the larger one, the result," he says "is a loss of 100° temperature." He speaks as if this were all lost, but it is out of this 100° that all the useful effect is realized, and it is this that has to be attended to to get an economical engine.

Now let us see what has become of this 100° of heat—we shall have to use the word heat, as temperature only expresses intensity—but the heat of steam is a positive quantity, for the heat that will make one pound of water one degree hotter, is equivalent to the work of raising 772 pounds one foot high.

For simplicity we will take a single cylinder engine; say the cylinder has a capacity of six cubic feet, and that there is admitted into it one cubic foot of steam of 75 lbs. pressure; to this will have to be added the pressure of the atmosphere, 15 lbs., making 90 lbs., and this is expanded to the full extent of the cylinder, and say it has lost 100° of temperature. The above cubic foot of steam contains six cubic inches of water, and has lost 100° of heat; or six hundred inches have lost one degree; six hundred divided by 27 gives 22.2 lbs. of water one degree hotter: 22.2 × 772 (Joule equivalent as above) gives 171,384 pounds raised one foot high, and if the operation took one minute, then 171,384 divided by 33,000 gives 5.2 horse power as the energy expended by the expanded steam. This is the total energy: but what has become of it? Part has been used to draw a train, or propel a boat, or do some useful work; and some of it has leaked through the cylinder, or passed through the sides of the cylinders by conduction and radiation, and it is to prevent this that the steam jacket is used—a thing he inquires about, and of which much could be said if this were not already too long.

C. R.

BOSTON, MASS., *Feb. 26, 1877.*

Editor ENGINEERING NEWS:

SIR.—Allow me to congratulate you on the improved appearance of ENGINEERING NEWS; I like the paper better every week.

How would it do to call out the practice of *surveyors of work* and their rules of thumb for measuring plastering, brick-work, etc., etc? These rules vary in different localities, and all engineers are obliged to bend to *custom* in these matters as things now stand.

J. FRANCIS LEBARON.

PORTAGE, WIS., *Feb. 23, 1877.*

Editor ENGINEERING NEWS:

SIR.—Business for the year past has been the worst I have ever witnessed, but I cannot afford to do without your paper. I am no longer Co. Surveyor. I would not run for the office last fall, nor do I intend running for it again. I agree with you in a desire to see the office abolished, or something done towards compensation. Our laws allow only $3 per diem and mileage, whereas your state allows $6.

I find that there are no less than ten surveyors and civil engineers in this county, five of whom are qualified to use the transit and level. I have used the transit on all surveys since 1856, but am the only one that does; the present incumbent is a compass man, who was my predecessor and who, together with *his* predecessor, only recorded one survey during their two terms (four years) of office, and I do not think that I did five surveys more than I should have done, through being the County Surveyor.

H. M.

NEW LONDON, WIS., *Feb. 28, 1877.*

Editor ENGINEERING NEWS:

SIR.—The original plat of the village of Waupaca, Wis., and the several additions, were originally surveyed by several different surveyors. Twenty years of undisputed possession gives title to land in this state. In 1856 the village Trustees ordered a surveyor to make a re-survey and map of the whole village. His survey differed materially in some respects from the original surveys; but it has never been disputed by action at law, or by legal process. Ques. Must a surveyor at present conform to said survey, or must he give heed to *original* boundaries, if any are found?

B. F. D.

Wherever *original* boundaries can be indisputably proved we think they will govern present surveys. A village, town, or city council have no authority to rectify a recorded plat without the consent of the owners, and any survey authorized by such a body will not affect well authenticated original boundary lines.—[ED.

KEOKUK, IOWA, *Feb. 27, 1877.*

Editor ENGINEERING NEWS:

SIR:—In Trautwine's Engineers' Pocket-book (1874 edition), p. 275, foot note (on Trusses), he says: "De Volson Wood, Professor Civil Engineering, University of Michigan, objects to the writer's 'calculations on strains in bridge trusses.' The professor sent his reasonings on the points, but they were, unintelligible.'" I think you would likely benefit a number of your readers by giving either Prof. Wood's or Prof. Greene's views in an *intelligible* form, so that ordinary readers (and Mr. Trautwine) can understand them. Trautwine truly says in his preface, that most of the writings on mechanics and engineering are not intelligible to any but accomplished mathematicians. In foot note p. 196, he says that to advertise and sell such books (referring then to Prof. Moseley's writings, and others) as being adapted to use of practical men, is sheer swindling. See also foot note p. 198; also foot note p. 286, referring to Rankine. Trautwine suggests, p. 292, that professional journals be the medium of reporting observed cases of decay of timber by the *contact* of various kinds. In foot note, p. 342, he says: "We know of no book to which a practical man can refer for any such information as we here endeavor to impart on this subject—pressures in stone bridges." There are many other hints in Trautwine's *practical* work to which I could refer you, but the above will suffice to show how your valuable enterprising journal will, no doubt, be a desiderated medium of ventilating such matters and keeping the profession and other interested persons *early* informed of the most recent information on all such pertinent matters, so that they shall not have to wait for new books or revised editions to issue to disseminate such knowledge.

Keokuk is talking of waterworks, also a revival of the Keokuk, Iowa City & Minnesota R. R., the construction of which has been for some time in abeyance. The car shops of the St. Louis, Keokuk & Northwestern R. R. are likely to be established here if the city will grant the site. The gas question being in order. Keokuk citizens think $4.50 too high for that commodity, and want a reduction. The river is open here and packets are running to St. Louis.

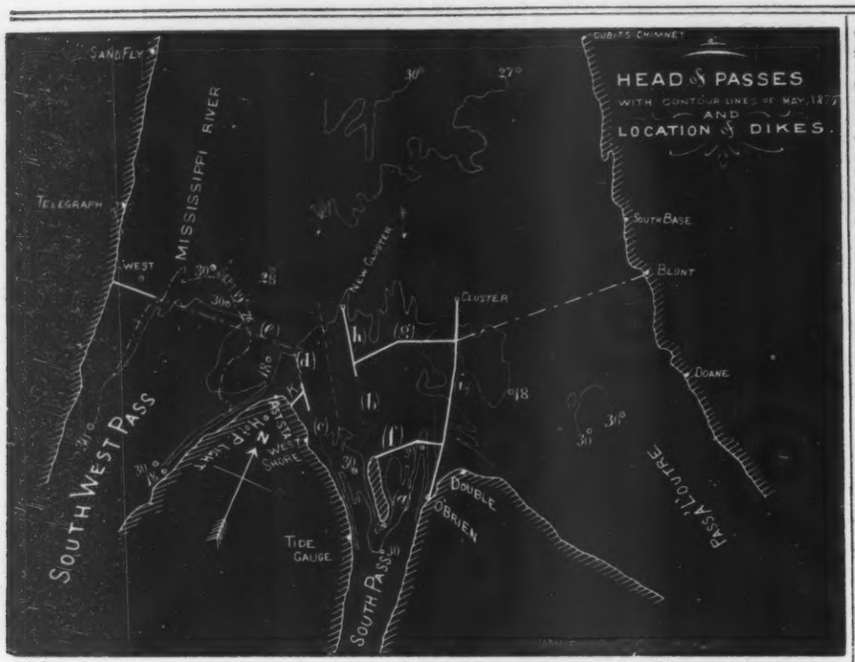
ALEX. BLACK.

NEW YORK, *Feb. 28, 1877.*

Editor ENGINEERING NEWS:

SIR.—The prospects in New York seem to be quite hopeful for the summer. Business men now say they are only waiting for the politicians to settle their little differences and then, as soon as warm weather comes, they believe all business will take a fresh start and become very brisk indeed. Engineers share also in this hopeful feeling. Quite a number of engineering projects will probably be hatched out by the warm weather and agitated for the next few months; labor on a number of suspended works may be revived again and those in operation will be pushed forward with renewed vigor.

The work, under General Newton, of removing harbor obstructions has been discontinued through the winter, owing to the ice in the harbor. But it is expected to begin again soon with renewed activity. A great many people supposed that, with the successful explosion at Hell Gate, last fall, the work was finished, and, as soon as the fragments were removed, the way would be clear for all vessels to enter our harbor from that direction. Unfortunately, though, that is not the case. The work accomplished by General Newton is but the first grand step towards the solution of the question of a second entrance to our excellent port, for vessels of all sizes, which will place us several hours nearer European ports, but it is only one step towards the attainment of this end; millions must still be expended. The next point of attack is to be Flood rock, where considerable work has already been accomplished. General Newton had laid out his plans for this summer, and made his estimates for this work. Unfortunately Congress did not see fit to furnish half the sum which he felt was necessary to complete what he wished to accomplish; he expects, though, to do more with the sum received than at first seemed possible. The only result of the niggardliness of Congress will be that New York will be obliged to wait so much longer before its harbor is perfected. It does seem a pity that Congress will be so miserly in furnishing money for such works of national importance as this, and at the same time be ready to squander millions in subsidiz-



ing railroad companies which would inevitably collapse on account of their worthlessness, if the Government did not step forward and furnish them with the cash to perform the work and afterwards present them with the ownership.

Since the injunction against the New York Elevated Railroad has been set aside, laborers have been working night and day to extend the road from its former terminus at the foot of Greenwich street, across the Battery to South Ferry. The company evidently fear a *coup de main*, and wish to prevent it by finishing the road. It is expected that cars will be running across the Battery by the end of the week.

In the meantime the other projects for rapid transit are languishing; some from legal difficulties, and some from lack of funds. Everybody desires rapid transit, but nobody wants the roads in his street, and will fight it as long as possible, if there is any danger of its coming there. t seems, however, as if the question of rapid transit for New York were to be solved by a general system of elevated roads and not by underground roads as in London, owing to the great difference in the cost of the two systems.

Work on the East River bridge progresses slowly. The foot bridge from anchorage to anchorage has been laid for over a week, and persons crossing at Fulton Ferry have usually had the opportunity of watching the progress of somebody walking along unconcernedly, two hundred and fifty feet above them. A few reporters have taken the trouble to cross on this foot-bridge in order to see what their sensations would be. One of them said Mr. Martin, the superintendent, gave him permission because he did not expect the reporters would give him any peace until they had all gone over, and some half a dozen had broken their necks by falling off or jumping off. The foot-bridge is for the convenience of the workmen in going back and forth while engaged in forming the great cables.

City work seems to be very quiet just at present. Nothing is heard of any works of importance. The good inhabitants are becoming very anxious to see some signs of the proposed bridge over the Harlem river at One hundred and thirty-eighth street. But all such works take time, and cannot be driven.

The bridge at Poughkeepsie also begins to look like a reality, although at one time it was doubted whether it would ever be more than a project. The first caisson was successfully launched a fortnight ago, and this will be followed up by more work.

Brooklyn has lately been called up n to mourn the loss of one of its most esteemed citizens, Mr. Cyrus P. Smith, the President of the Union Ferry Company, and formerly President of the Brooklyn City Railroad Company, a man who has been one of the most instrumental in the rapid growth and prosperity of the city, by his liberal policy in providing all the facilities possible in his powerful position for the rapid, convenient and safe communication between the two cities of New York and Brooklyn. May his successor prove to be as valuable to the interests of the City of Churches as he has been. E. A. R.

PORT EADS, LA., *February 16, 1877.*

Editor ENGINEERING NEWS:

SIR.—I regret my inability, for want of time, to give you a full and detailed history of the construction of the works at the head of the Passes, and of the results thus far attained. I will give you briefly a few explanatory statements to make the accompanying chart intelligible.

Referring to the illustration below, with works noted by letters, (*i*) was built first, a substantial dyke, and intended to deflect into South Pass some of the volume of Pass a L'outre, but the result was not as favorable as was anticipated, and it was decided to select the worst channel as the one to be improved; but as the works should be tentative, they were not built in a permanent manner. *f*, *g*, *h*, and *k* were constructed by laying a foundation mattress and erecting on it a mattress tilted against a row of braced piles. Those works demonstrated that the right plan had been adopted, although they were by no means water-tight, and allowed nearly half of the volume to pass through them.

The general principle lying at the foundation of the plan was this: "Slope is the measure of friction, and generally the measure of velocity: increase the slope and you increase the velocity also the frictional power of the current, and also its abraiding and erosive and carrying power." Imagine a water-tight dam thrown instantly across the head of South Pass; what would be the result at high river with a fall to the gulf of say two feet? The Pass or the level of the water immediately *below* the dam would at once drop to the level of the gulf. The water immediately *above* the dam would be raised *above* its normal height, as the other two passes could not accommodate the volume shut out of South Pass, they being filled their whole length and area by their own volumes. This would give us a head of water of say three to four feet. Now remove the dam as quickly and what is the result?—an extraordinary deepening through the shoal.

Again, we have learned that a funnel-shaped entrance is objectionable; we therefore *narrow* the entrance to South Pass, and make the entrances to the other passes as much funnel-shaped as possible.

The dams *f g k* being temporary, a permanent dam was built at *a*, one is now being constructed at *b*, one is built at *d*, and a sill 70 feet wide laid across S. W. Pass at *e* to preven deepening by the head of water made above our contracting works.

The river rose on the 27th of January, reaching half flood at New Orleans on the 4th of February.

At the jetties, and through the whole length of the Pass, the channel is rapidly improving. steamers and sailing vessels drawing twenty feet are passing out without any trouble, and present indications show that we will very soon have a deep wide channel, and a permanent one also, between "New Orleans and the sea." E. L. CORTHELL.

[*Written for Engineering News.*]

CEMENTS AND CONCRETE.

BY BERNARD R. GREEN, C. E., PORTLAND, ME.

(*Continued from page 53.*)

The setting of hydraulic limes and cements in presence of water, occurring with greater or less activity, is a kind of crystallization, combinations taking place between the lime, magnesia, silica and alumina. Water here assists in the completion of a chemical action that is begun during calcination, the greater part of it, when in proper proportion, being thus chemically combined. Induration in hydraulic mortars proceeds simultaneously throughout the mass; its permanence is proved by the experience of many years. The chemical actions involved, so far as understood, are explained in treatises on the subject. With Portland cement it makes little or no difference whether fresh or sea water be used; with the natural cements fresh water gives greater strength, but the mortar may be immersed while soft in salt water. In any case mixing with salt water is liable to result in efflorescence upon the surfaces of open air works. We may mention here that the white efflorescences, which so frequently disfigure walls laid up in mortars of natural cement, are of various composition, mainly carbonate of potash or soda; are generally favored by dampness; but may be readily removed by scraping.

In the fabrication of mortars for either masonry or concrete, at all important works in this country, the Portland and the Rosendale class of cements are almost exclusively depended upon. We will therefore confine the further treatment of our subject to such mortars and concretes.

It will be borne in mind that all that relates to the materials, composition, durability, etc., of mortars, must of course be of primary importance to the concretes into which they enter.

The use of common lime in conjunction with the cements operates to increase the bulk of mortar, so that, for equal volumes with large doses of sand, the mixture containing lime would be less porous, possess greater proportionate strength, and require a smaller proportion of the more costly cement. Engineers differ as to the ultimate economy of this as a general practice. The water used in mortars should always be clear and fresh—free from vegetable matter or clay in suspension.

To be most suitable for mortar the sand must be clean, hard and sharp, the particles not of too uniform size, nor withal too fine. These conditions are best answered by the silicious sands of the sea shore or river bed. Good sand is also found in banks or pits distant from the shore. Sand from the former sources is more likely to be well washed, though deficient in sharpness, while pit sand may be sharper, but injured, more or less, by an admixture of clay or vegetable mould—very dangerous impurities that cannot be too scrupulously guarded against. They may be deteeted by rubbing the sands in the palms of the hands, but with greater certainty by washing in clean water. The obvious advantage of variety in the sizes of particles is, that such sands are more compact, contain a smaller amount of interstices or voids, and hence require less cement to unite them into a mass of almost perfect solidity. A bird-shot uniformity of size may be overcome by a mixture of different sands. This is best accomplished by experimenting with sieves upon small quantities well dried, to find the proportions in which they should be mixed to produce the greatest weight or density. To do this, measure a cubic foot of the coarser sand, well shaken down, and then gradually add and stir in the next finer grade as long as no increase of volume occurs when shaken down. The proper proportion of the finer sand per cubic foot of the mixture is thus determined, and the quantity that this mixture will take of a still finer grade may then be similarly found.

One of the most satisfactory means of arriving at the value of a sand, or a mixture of sands, with a given cement, is to make small test blocks of the mortar and compare their behavior and strength with those of the corresponding standard mixtures.

As more or less misapprehension as to the actual effect of moisture upon the bulk of sand is always to be found, it may not be amiss in this connection, to give the following from General Gillmore:

One cubic foot of mixed silicious sand,
damp and not compacted, weighed..... 87 lbs.;
damp and compacted, " ..... 97 lbs.;
dried in oven and not compacted, weighed.. 97½ lbs.;
dried in oven and compacted, " ..105½ lbs.;
compacted and afterwards dampened " ..112¾ lbs.;

Mortars made of pure or *neat* cement, with a proper quantity of water, always attain a greater hardness and strength than if mixed with sand. Whether with or without sand, a deficiency of water results in imperfect chemical action, while a surplus renders the hardened mortar porous from the final evaporation of the uncombined water. Experience is the only reliable guide in determinlng the proper measure of water, as it varies with the nature of the work, and the quantity and moisture of other ingredients. By far the strongest mortars of either Portland or Rosendale cements, with or without sand, result from mixtures in a state of incoherent dampness, but it is not always practicable to so work them.

The weakening effect of sand in mortars is not in proportion to its quantity, within reasonable limits, and it is therefore so far an economical substitute for cement. Sand is an adulteration, limited by the strength and density required, a remark equally applicable to concretes, which we shall consider presently.

The best proportions by volume of any given sand may be ascertained by measuring the quantity of water that a compact measure of it, in an ordinary state of humidity, will contain without increase of bulk. Such quantity of water shows what bulk of cement paste is required to make with the sand a solid mass. The possibilities of slight shrinkage and especially of imperfect manipulation, however, render it generally advisable to increase this amount about one-half. A common dose of coarse silicious sand in ordinary work is, by volume, 2 to 2½ parts for Rosendale, and 3 to 4 parts for Portland cement. An inordinate addition of sand naturally causes porosity, which may be thus extended to the final ruin of the mortar.

It is probable that, with silicious sand, a slight superficial coat of silicate of lime is formed on its particles.

Masons dislike to use Portland cement mortar on account of its deficiency in that adhesive consistency peculiar to mortars of lime or natural cement, which requires it to be handled more carefully on the trowel.

Warmth considerably accelerates the hardening of hydraulic mortars; it is therefore necessary to conduct tests of quickness at a uniform temperature, say 60°, in order to arrive at fair comparisons.

Mortars never fully recover from the effects of jarring or otherwise disturbing the process of crystallization, and their ultimate strength may in this way be very seriously impaired.

In order to guard against the many chances for an accidental or intentional supply of inferior or damaged cement, a perfect system of tests should be instituted at all important works, and carefully applied to every new lot of cement received and also to any that may have been long on hand. Judgment must be the guide as to how many barrels shall be tested in any one lot, to the end that the consumer may be satisfied concerning its precise quality. Such tests may be conducted at a comparatively very small expense by an ordinary, if faithful, laborer, provided with the proper apparatus and instructed in a simple routine. A quite complete series of tests consists, in observing, first, the behavior of cement while hardening under water—as to the time occupied in setting,—the hardness attained, and whether it swells or cracks (indicating an excess of quicklime); secondly, its tensile and crushing strength per square inch; and, thirdly, when thoroughly set, its resistance to the weather.

A successful resistance of the first test is an indication that it will fairly stand the third. The tensile strength is generally more easily and fairly ascertained than the resistance to crushing, but the latter more desirable quality may be approximately estimated from the former. It is therefore usual to rely upon only two tests conducted in the following manner:—

The neat cement, or mixtures with sand, are made into very stiff mortar and at once pressed into moulds of two forms, preferably of brass or galvanized iron.

(*To be continued.*)

STEAM ON STREET RAILWAYS.

It is now more than a score of years since street railways were first put in operation in our principal cities. In that time we have seen little change in their construction, equipment and method of maintenance. The cars are, in many cases, somewhat handsomer than at first, but the means of locomotion is still by horse power. Dummy engines have occasionally been placed on suburban lines, where the route was long and removed from crowded thoroughfares, but they have not increased materially in numbers until quite recently, having generally been laid aside after a short trial. The steam engine is much superior to the horse for the purpose of drawing a car, can be easily controlled for starting and stopping, even to the extent of speedily arresting the motion by reversal of the engine as an auxiliary to brake power, can handle a greater load without taking up more street space, can take the place of numbers of horses, requires no food and extra attendance when not at work, and has a much longer life with decent care. We must therefore search for some reason why steam has not been generally introduced on street railways.

The construction of small steam engines of various powers has become wide-spread, and there are many very satisfactory and economical types in use. The firm which shall manufacture and successfully introduce small motors for street cars will do a handsome stroke of business. The field for their occupation is immense. The engine should be simple in detail, strong in its parts, not likely to get out of order with decent care from a driver of moderate ability, quiet in operation and reasonably economical of fuel. The only objection to their employment appears to be the fear that they will frighten horses. Any inconvenience from this source, is, at the most, temporary. The horses of a city will soon become used to the sight of steam cars on the public streets, as they have already, in many instances, become used to the locomotive. And they will be broken to the former the more readily as there will be none of that roar of the train and cough of the exhaust which accompanies the latter.

The evidence all goes to show that this trouble has been much exaggerated. The *Railway Age*, in an article on this subject, states that the Citizens' Passenger Railway Company, of Baltimore, have been, for some months, testing a dummy on some of the busiest streets of that city, and are so well convinced of its economy and general advantages that they have applied to the City Council for permission to operate steam motors on all of their cars. The testimony of a majority of the business men is that horses will soon cease to be annoyed by the engines, if these are generally introduced, and is decidedly in favor of the change. Those horses which were frightened at first, now do not mind them. It is further testified that the dummy can be handled more readily, can be backed with ease in a crowded street, and can keep out of the way with greater facility than can a horse car.

No more men would be required on a car, although the engine driver should possess more intelligence than is absolutely requisite in the present driver, and might command higher wages. The force of stable men would disappear, being replaced by a few cleaners and other men necessary to an engine house. But little modification in the repair shops of the company would be called for.

We saw a dummy in use on Market street, in Philadelphia, last summer, at the time of the great crowds of the Centennial Exhibition, and its operation was attended with no difficulty. That Passenger Railway Company are so well satisfied with the results of their experiment that they have procured several additional steam cars, of the Ransom pattern, and are now about to put them on their lines. They have some of different designs, though how they differ we have not been informed, and will finally adopt that type which works most satisfactorily.

As facts are more convincing than any theory, we give the following comparative statement of cost of the two systems of steam and horse power in Philadelphia. The Market street line has as steep grades as are to be found in most cities.

Feed and care of eight horses one week	$24.00
For pay of driver at $2 per day for seven days	14.00
Total cost of horse car in one week	$38.00
Fuel for one week, 1¼ tons	$8.75
Salary of engineer one week (say at)	18.00
Total cost of steam car in one week	$26.75

After this problem has been worked out, to the satisfactory substitution of steam for horse power, the question how to warm a street car so that it shall be reasonably comfortable in cold weather is answered without further trouble. The boiler in one end of the car will readily furnish steam or hot water, if it is not rather thought expedient to use exhaust steam for heating purposes. The latter method would not answer where a car was likely to remain standing for any length of time at a terminus. The subject of heating these cars has been lately discussed in the New York papers, interest having revived in this matter by reason of the cold of December and January. Several inventors have come forward with expedients, such as hot-water receptacles under the car, which should be replenished at the ends of the route or at convenient intervals, balls of cast iron or a mass of the same material heated very hot and placed in a similar receptacle, etc.

Strange to say there have been found physicians who argued that heating would be unhealthy, in that warm air would tend to promote the contraction of contagious diseases in the crowded cars. So that the Board of Aldermen of the city of New York finally settled down to the resolution "to direct the Board of Health to compel railroad companies to keep, while *en route*, the front doors of their cars constantly closed in cold or stormy weather, and that clean straw be provided for the floor of every car in such quantities and seasons as the Board might direct," a most impotent conclusion of a well advised attempt to ameliorate the present chilly condition of a horse car in winter. Which is the healthier, to be cooped up in a car with from twenty to forty others, when every door and aperature is kept closed, in order that the animal warmth of the crowd may have some effect on the interior air, this air being respired over and over again and polluted with the various emanations from the occupants, till every one becomes dull and weakened in vital force; or to occupy a car so warmed that air must circulate and pass out to enable warm air to come in?

When steam cars are once successfully introduced upon street railways, we shall look for the adoption next of traction engines for handling the heavy loads, which are now conveyed from foundries and iron working shops by the aid of large teams of horses, taking up much space and seriously interfering with public convenience. These engines have been used in considerable number in some of the cities of England and Scotland but we believe the only shape in which steam appears in the streets of our American cities, except as previously noted, is in driving the heavy road rollers, so effective in consolidating the roadway.

EGAN, the architect of the Court House has claims of $26,000 for extra plans, and about $5,000 more for superintendence.

WORK for the season has been commenced on the New Court House. It will require $450,000 to enable contractors to finish the work satisfactorily, a sum which in the present financial condition of Chicago and Cook County will not very likely be forthcoming.

BLUE GLASS, to judge from the papers, is to have its healing and health promoting qualities very thoroughly tried by the public. It has become quite the fashion. It seems a little curious that the same blue rays will according to Pleasanton's book, promote the growth of animals and plants which are desirable and of use to man, while they are destructive to weeds and vermin-flies and such petty annoyances. His deductions from his experiments do not appear to be logical.

THE American Society of Civil Engineers held their second meeting of the month at the rooms of the Society, No. 4, E. 23d St., New York city, on the evening of the 21st of February.

The evening was entirely devoted to the subject of the Ashtabula Bridge (which is gaining in interest as the facts concerning its construction are eliminated, and the discussion upon the merits of various systems of bridge building progresses); a paper giving the results of his observations, by Mr. Chas. McDonald, was read, and a general discussion by several members was participated in, after which the meeting adjourned.

(Our correspondent has sent us an abstract of the paper and of the discussion, together with a diagram, but as we expect that every reader of the NEWS, who takes any interest in the subject of the Ashtabula Bridge, intends to possess a copy of the forthcoming book containing the complete report of the coroner's jury, which is advertised by us in another column, so we do not expect to publish much, if anything more upon the subject.—[ED.

WE need hardly call attention to the increasing amount of contractors' intelligence that we are now publishing, nor of the importance of this information as furnishing a basis for future bidding from a comparison of the figures given. We are very much obliged to the parties who have so kindly sent us the information in answer to our request, and we hope to be able, as the season advances, to make this department of our journal one of very great value to a large class of its readers.

AT the meeting of the American Institute of Mining Engineers, on the evening of the 27th ult,, in the rooms of the American Society of Civil Engineers, in New York, over forty new members were elected, from all parts of the United States and Europe, swelling the membership to more than six hundred. The programme was announced for the rest of the convention, which includes a visit to the new Bergen tunnel of the Delaware, Lackawanna & Western Railroad.

CIVIL ENGINEERS' CLUB OF THE NORTH-WEST.

The 73d regular meeting of the Club was held at the Sherman House Club Rooms, Chicago, on Tuesday, the 6th of March, beginning at 4 P. M.

The chair was taken by the President, Mr. E. S. Chesbrough.

Mr. L. P. Morehouse, the Secretary, read the minutes of the previous meeting, which were approved, after which the Club proceeded to elect Mr. Charles Sooysmith, proposed some three months back, but whose absence in Europe delayed his election, the necessary papers having been sent to him and returned.

The Secretary reported the receipt of the "Annual Report of the City of Allegheny," Mr. Charles Davis, City Engineer, and the "Annual Report" of the Chief of Engineers, U. S. A.

At the conclusion of some remarks by the President, Mr. L. Y. Schermerhorn proceeded to read his paper on the "Improvement of Eagle Harbor," Lake Superior.*

C. W. Durham, C. E., presented a petition, for the signature of members, praying Congress to appropriat the sum of $50,000 to establish a colony near the scene of the latest Arctic researches, in order to complete the same to the fullest extent possible.

A vote of thanks was unanimously tendered to Mr. Schermerhorn for his interesting paper, and the meeting adjourned for informal conversation.

Written for "Engineering News."

DESCRIPTION OF THE WATER WORKS AT BANGOR, MAINE.

BY L. H. EATON, C. E.,
Engineer Bangor Water Board.

These works are situated one and one-half miles from the post-office, in Bangor, and are upon the plan of direct force, known as the Holly system. There are four piston pumps, of twelve inches diameter of cylinder and twenty-seven inches stroke, mounted at the four corners of the base of a heavy cast-iron frame and connected to a crank shaft above. The shaft is carried in boxes on the upper arched portions of the frame, and the two pumps on each side transverse to the shaft are connected to the same crank pin, the piston rods making an angle of 45° with the vertical; the two crank pins, at opposite ends of the shaft are so disposed that the pumps take suction and discharge at eight equidistant points for each revolution, securing a uniform flow into the main. Either pump may be disconnected so that one or more may be run at any one time. These are supplemented by an elliptical rotary pump of the capacity of sixteen gallons per revolution; the whole set

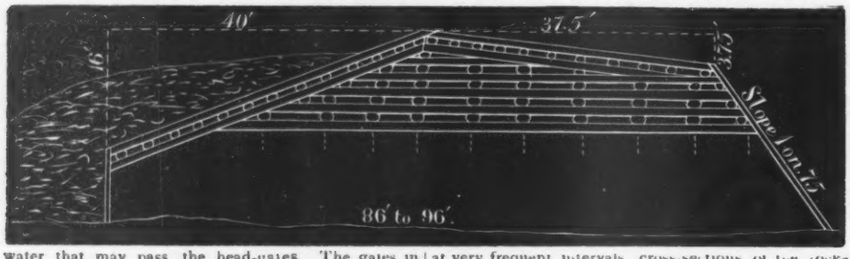
* This paper is printed in full on page 65.

is capable of easily supplying five million gallons in twenty-four hours.

The pumps are driven by three American Turbine wheels, made by Stout, Mills & Temple, Dayton, Ohio., eighty-four inches in diameter, working under a varying head of from five to fourteen feet, according to the rise and fall of the tide. Thus far it has only been found necessary to use two of these wheels at once, and then with a gateage of from one-fourth to one-half their capacity, accoading to the tide, even in case of the largest fire experienced since the construction of the works. In addition the works contain a compound steam engine, built by the Holly Manufacturing Company, the high pressure cylinder being fourteen inches diameter with a piston travel of twenty-four inches, and the low-pressure cylinder being twenty-one inches diameter and thirty inches stroke. They may both be worked at high pressure when necessary.

This engine is supplied by steam by two horizontal tubular boilers of five feet diameter and fifteen feet long, each having fifty-four three-inch tubes, and set in a room adjoining the engine and pump room, with a smoke-stack outside, seventy feet high. The boiler-room is thirty-nine by forty feet, the pump and engine-room is fifty feet square, and the wheel-house, adjoining the pump-room, on the end opposite the boiler-house, is thirty-nine by forty-four feet over the machinery floor, of which a tenement is finished off for the residence of the engineer.

Water is received into the wheel-pit from the head-race through two arches of 190 square feet area, causing the current into the wheels to be very slight, and passes from the pit into the tail race through arches of 150 feet area. The current from the wheels is very much more rapid as the tail race descends rapidly. These arches are so arranged that the water will at all times cover the entire intrados, thus excluding the cold air and preventing ice forming in the wheel-room or flume. The outer or coarse rack is so arranged that it is entirely below the surface of the water in the pond, thus allowing drifting substances to pass over the dam. The fine rack is so situated that anything that passes the outer rack and the head gates draws by it and passes through the waste way of the flume into the river below; this waste way is intended also to provide for any excess of water that may pass the head-gates. The gates in the wheel cases are controlled by one of Holly's automatic governors, which, by means of belts and gearing, opens them when the pressure is diminishing in the pipes, and shuts them when the pressure is increasing, a very ingenious piece of mechanism and admirable in its operation.



The pressure in the pipes is governed by a safety valve leading from the force main, which valve may be weighted to whatever pressure may be needed. For instance, the domestic pressure is one hundred and ten pounds; if fire pressure is needed on high service, say two hundred and thirty feet above the works (our highest service), the engineer has simply to weight the safety valve to its proper requirement and, setting the indicator of the governor at the required pressure, it at once runs up. If the movement be too slow to meet the need for an immediately increased supply of water, it can be expedited by the engineer turning the governor by hand.

Communication is had with the works by means of telegraphic gongs, that the engineer may be informed of any want of increased quantity of water for fire or other purposes.

The water flows from the flume to the filter through a revolving screen of copper wire netting, which catches and passes off into the wheel-pit any saw dust or other small substances that may be held in the water. The filter is of two chambers, each twelve and one-half feet wide by one hundred and fifty feet long. From these the water passes into a filtered water chamber, from which the suction pipes take it to the pumps. The filter bed is composed of brick, gravel and sand, and yields sufficient water to supply the demand of the largest fires. The buildings are heated by steam; therefore, as our boiler is always fired up in winter, if the wheels become clogged with anchor ice, or an accident happens to them, immediate resort may be had to steam power.

The system of mains comprises twenty-one and one-half miles of pipe,—cast-iron, tar coated;—the force main is sixteen inches in diameter, and extends from the works one mile into the city, at which point it is reduced to twelve inches, having, before reaching that point, been relieved by numerous secondary mains. The distance from the works to the end of the most remote pipe is about two and three-fourths miles. There have been set one hundred and forty-six hydrants, principally of the Holly pattern,—a few Matthews hydrants are in use.

The dam for the water power is at a locality known as Treat's Falls, one and one-half miles from the post office; these falls were simply rapids with a natural descent of about twenty-two inches. The tide has here a mean rise and fall of about twelve feet. The crest of the dam is eight feet above mean high tide, and has an overfall nine hundred feet in length between abutments; the river bottom is of slate ledge, irregular in its contours, with a trend crossing the direction of flow of the river at an angle of about forty-five degrees. The dam is of crib work filled with stone. Into the irregularities of the ledge, timbers were fitted until the work was brought up to a height to admit of the regular crib work being fitted upon it, the entire structure was thoroughly bolted together with seven-eighths iron bolts, and solidly packed with rubble, common field stone and stone from the river shores; it was then covered with six-inch hemlock plank, the toe filled and covered to a depth of from eight to ten feet with gravel and stone. The accompanying sketch will give the form of the dam, and and an idea of its structure.

The dam was commenced at each end and extended into the river by placing tier after tier of logs from the bottom up, until the water at low tide was too deep to permit men to place the logs. The remaining gap, of some three hundred feet, was then carefully sounded out at very frequent intervals, cross-sections of the rock-bottom thus obtained and cribs were built to fit the same. These cribs were as long as the breadth of the dam, some fifteen or twenty feet wide, and came a little above low water level when sunk. They were successively floated to place at high tide, moored in position, adjoining the portion already partly built, and sunk by loading with stone. Jogs or shoulders on the faces in contact kept the sinking crib in line, while strong tackle drew it firmly against the end of the dam. On the receding of the tide it was filled completely with stone. The entire gap was thus filled with cribs, which came above the low water line on the lower side of the dam. A coffer dam or temporary construction was formed, to stop the flow of water over this portion and cause it to run over the completed part. As the cribs were built hemlock posts 12" × 14", set eight feet from center to center, and about six feet from the toe or upstream line of base of the dam, were framed in vertically, in some cases being permanently fastened, and in others being fitted into deep sockets and then removed, to be put in when the dam was so far finished as to require the coffer to be planked up. This space was left to permit the passage of rafts and logs until the water could be turned through the sluice way. The posts were then put in place, the planking put on the upper side, and the coffer was thus completed. This was done under difficulties consequent upon a heavy rise in the river, but was successfully accomplished. The space thus laid bare was built up with logs, care being taken to bond the whole well together, and the stone and planking was added. After the dam was completed, the coffer planks were removed and the posts sawed off. The abutments, of granite masonry, are ten feet six inches above the crest of the dam, with provision, in case of an extraordinary rise in the river, for flash boards upon the abutments and wings of two or three feet more. The expense of the dam, abutments and wing walls has been about one hundred and fifty thousand dollars, and it is considered one of the most substantial dams in the country.

There is, at the lowest stage of the river, in the summer drought, a nominal horse power of forty-five hundred at mean high tide and at low tide, of eighty-seven hundred; this stage usually lasts but about six weeks in the summer, and occurs in the winter for a shorter period, ordinarily about four weeks. This would give at the respective stages of the tide an effective horse power of about thirty-six hundred and seven thousand. The larger head has a duration of from one-third ebb to two thirds flood, or for a space of about eight hours out of the twelve. Only about forty-five horse power is used in driving the pumps for ordinary domestic service. The dam is so built that it can be readily increased in height when greater power is needed to supply factories and mills.

The line of the E. & N. A. Railway passes in the immediate vicinity of the dam and will afford facilities for transportation of freight, without damage. Boats and sailing vessels of eight or ten feet draft can also come to the works to discharge and receive freight, while twenty or more feet of water is found at the railroad wharves two miles below.

A fishway is being constructed upon the easterly end of the dam adjoining the abutment after plans furnished by C. G. Atkins, Esq., engineer of the U. S. Fishing commission, at an expense of about six thousand dollars. It has the general form of a spiral stair case, and will be ready for service in season for the spring run of fish.

GENERAL PROPERTIES—DETERMINATION OF DIMENSIONS.

The method of determination of the proper dimensions of the various component parts of constructions of iron and steel has, until recently, been as follows: Having determined by the *statical* calculation the greatest stress, $max\ B$, which can ever act in the part in question, we divide this stress by the assumed allowable stress, b per unit of area, and thus obtain the required area of cross-section

$$F = \frac{max\ B}{b} \quad (1)$$

which the piece in question must have in order to safely resist the given stress.

In general the value of b is taken invariable, no matter whether the stress is caused by constant or *dead* load, or whether the load and, therefore, corresponding stress, undergoes sudden changes, as in the case of bridges, rails, axles, etc. In Prussia, for example, the value of b for iron is almost universally assumed at 730 kil. per square centimetre (10,400 lbs. per sq. inch), and this value is assumed indifferently for tension, compression, and shear.*

Gerber, in the calculation of the Mainz bridge, was the first to depart from the above practice. He assumed for each member of the construction a different value of b, taking it less as the proportion of the stress due to moving load to that due to the dead load increased.

When a member is submitted also to alternate tension and compression, formula (1) was still considered as holding good, the *absolute* greatest value being taken for $max\ B$. The American practice has, in such case, been a more rational one. According to it, if $max\ B$ and $max\ B'$ are the greatest strains of opposite character, then

$$F = \frac{max\ B + max\ B'}{b} \quad (2)$$

where the usual invariable value of b, as above, is however assumed. Numberless axle failures, boiler explosions, bridge failures, etc., admonish those interested to search after the causes of these occurrences. Such occurrences are the more noticeable, inasmuch as a coefficient of safety is always used which, it would appear,

*These remarks do not apply to present American practice.—Different values of b are taken for tension, compression, etc., though constant for each.

ought to exclude every danger. The question, therefore, presses hard upon us, whether our iron bridges in general really possess the durability assigned to them. We have, as yet, no experience in this direction to appeal to, since the application of iron in bridge construction reaches back hardly a hundred years. In the year 1874 the society "Deutscher Architecten-und Ingenieurvereine" determined to seek, by systematic and similar observations, a solution "in order that those engineers engaged in the maintenance of iron structures may not be confronted with catastrophies."

The foregoing is an extract from a forthcoming translation of Prof. Jacob J. Weyrauch's book, on "Strength, Dimensions and Calculation of Iron and Steel," with reference to the latest experiments, by Prof. A. Jay DuBois, author of "Graphical Statics."

A BILL has been introduced into the New York Legislative Assembly, to provide a "State Board of Health," in reference to which *The Sanitarian* presents the following statistics and comments:—

The local and public causes of destructive diseases which strike down the most valued classes of inhabitants, as well as the poor and those who are least protected, because unnoticed, are every year endangering the loss of lives which the State should protect and save by the practical application of sanitary knowledge for the prevention of such causes of disease and mortality. In the State of Massachusetts the eminent financier and economist, Hon. Mr. Plunkett, stated, after a few years' operations of the State Board of Health, that in single large villages, the saving of life and health by agencies exerted by that Board had been worth more in cash than the entire annual expenses of the Board.

During the census year of 1870, New York, with a population of 4,382,759, had a recorded mortality of 69,095; and that number is, with good reason, believed to be considerably less than the actual mortality, because this State has no system of general registration of deaths. In the total record of mortality, 17,596 deaths (25.46 per cent.) were caused by zymotic diseases, which are the most preventable of disorders, and comprehending 6,930 deaths from diarrhœal diseases; 3,403 from scarlet fever; 2,029 from typhoid fever, and 864 from diphtheria, a disease which has so increased in prevalence since 1870, as, in 1875, to have destroyed not less than 4,000 lives.

Of the other causes of mortality—namely, the remaining three-fourths—11,598 died of consumption, and 8,158 from other diseases of the respiratory organs—and these diseases are largely dependent upon preventable causes, as well as the zymotic diseases. 2,664 deaths resulted from violence: burns, scalds, drowning, suffocation, explosions, "accidents," etc., etc., in the main due to the want of intelligently directed public measures for their prevention. Taking all together, of the total number 69,095 deaths from all causes, 53,902 from the eight categories above given are in large measure preventable by well recognized sanitary measures, such as no less than twelve States of the Union have established during the past few years.

Again, that this waste of life may be made still more apparent: of the total number of deaths, 69,095, for the year, 31,602 were of infants and children under 15 years of age; and of these 27,071 were under five years of age. That the loss in pecuniary value to the State from these 31,602 premature deaths may be duly appreciated, it is only necessary to remark that the cost of their sustenance from birth to death was a total loss—they died without living long enough to render any material return for the cost, and to this is to be added the expense of sickness and burial. By assuming that the average lifetime of the whole 31,602 infants and children was only five years, and that the cost of this five years' sustenance, sickness and burial was only $200 each, we have in this item a dead loss from premature deaths of children, $6,320,400.

Again, of the deaths enumerated for the year under zymotic diseases, 2,029 were caused by typhoid fever, a disease which kills most of its victims in the prime of life, at a time when the individual is of the most value to his family and the State. The average value of lives taken by typhoid fever (of both sexes), at a moderate estimate, is not less than $1,500 each. The loss to the people from this cause, therefore, amounts to over $3,000,000 annually—for there is no question that considerably over 2,000 deaths from typhoid fever have occurred annually in the State for many years, and of all the diseases enumerated, typhoid fever is well known to be entirely preventable by sanitary measures.

The more closely unsanitary conditions are examined, the more extensive do their ramifications appear, and in whatever degree the duration of life is diminished, in the same degree so much productive power is lost. And every community is poor and powerless in the inverse ratio to its standard average duration of life and health. Every death under the age of twelve years at least carries with it a positive loss to the community in which the individual has lived, because, previous to that age, sustenance involves a direct outlay, and if the life of the individual is preserved, a productive member of society is added and remuneration rendered. And as regards adults—if the probabilities of life in any community are so low as to give the average adult age at death below the ripe maturity of life, the proportion of widowhood and orphanage is increased, and the productive members of society are proportionately burdened, and thus it is that burdens are created and costs entailed upon the industrious survivors of every community in direct ratio with a high mortality.

CEMENTS AND CONCRETE.

BY BERNARD R. GREEN, C. E., PORTLAND, ME.

(*Continued from page 58.*)

One mould is a ring of about 1½ inches diameter and ½ inch width, immersed in a shallow trough of water as soon as filled, where are observed the tendency of the mortar to crack and the progress of hardening while setting. The latter action is noted by frequent applications of the end of a loaded blunt needle, called a testing wire, usually 1-12th inch in diameter, and weighing ¼ pound: but this test is less needed with Portland than with Rosendale cement. The other mould forms a flat I shaped brick, the standard cross-section of the neck being 1½ inches square, equal to 2¼ square inches. The testing apparatus consists of a scale beam provided at the short arm with a pair of clips fitted for clasping the heads of the brick. [The reader is referred to the treatise on Sanitary Engineering, now current in ENGINEERING NEWS, for a brief description of and drawing (Plate V, Figs. 16 and 17) of this apparatus; tables of strength of cements, etc.; and the application of concrete in sewer work.] After this test brick has arrived at the desired age, commonly seven days,—one in air, and six in water,—it is placed in the clips and exposed to a steadily increasing tensile strain, applied without shock or jar, by means of a sliding poise, or a spring balance attached to the extremity of the beam, and carrying a pan into which sand, shot, or water may be gently poured.

The test of strength with doses of sand generally obviates the necessity for tests of fineness and weight of the dry cement powder.

Resistance to frost may be rapidly tested by repeated exposures to freezing mixtures.

The following notes and tables of the strength of cements and mortars are, with the exception of those marked *, compiled from the experiments of General Gillmore, and of Mr. Grant, of London. Unless otherwise specified the test pieces were made of stiff mortar pressed firmly into the moulds by hand. Proportions are given by volume loosely measured.

TENSILE STENGTH.

Test pieces seven days old—first day in air, and balance in water—unless otherwise stated.

English Portland, neat, weighing 103 to 126 lbs. per U. S. bushel, sustained 239 to 406 lbs. per sq. inch.

Standard English Portland, neat, weighs 106 to 110 lbs. per bushel; sustains from 178 to 222 lbs. per sq. inch and requires 42 to 44 per cent. of its volume of water, to convert it into paste of the consistency of masons mortar, but more if the cement be fresh as it may then contain some quick lime.

English Portland.			Boulogne Portland.		
Cement.	Sand.	lbs. per sq. in.	Cement.	Sand.	lbs. per sq. in.
1	0.5	202*		0.42	232
1	1.0	177*	1	0.85	197
1	2.0	96*	1	1.13	139
1	3.0	68*	1	1.70	109
			1	5.00	35

Neat English Portland, at age of one year, about 500 lbs. per sq. inch.*

Rosendale Cement.

Neat	72 lbs. per sq. inch.
Cement 1, sand 0.6	51 " "
Cement 1, sand 1.8	33 " "
Cement 1, sand 2.4	22 " "

On one occasion neat cement varied in five lots from 18 to 65 lbs., and averaged 47 lbs. per sq. inch.

At the age of fifteen months, kept in a damp place but never under water:—Neat, 154 lbs.; with sand 1,—132 lbs.; with sand 3,—63 lbs. per sq. inch.

	lbs. per sq. in.
Neat, rammed, 25 days old in damp place	218*
" 1 day in air, 7 days in water	126*
" 8 days in air	197*
" 8 days in air, (single test)	227*

TRANSVERSE STRENGTH.

Test pieces formed by vertical moulds into rectangular bars of 2 × 2 × 8 inches; allowed to set one day in air under a pressure of 32 lbs. per sq. inch; afterwards immersed in salt water for 319 days; and then broken in a horizontal position upon supports four inches apart by a weight at the middle, gave the following results:

	Rosendale.	*English Portland.*
Neat	635 to 871 lbs.	1536 lbs.
Cement 1, sand 1	620 lbs.	1263 lbs.
Cement 1, sand 2	516 lbs.	950 lbs.

A thin paste of neat Rosendale, similarly treated, sustained from 613 to 692 lbs.

CRUSHING STRENGTH.

Blocks, 3½ × 5½ × 3 inches, seven days old,—first day in air, remainder in water. Area of compression, 19¼ sq. inches. Results in lbs. per square inch.

		Rammed.	*Not rammed.*
Boulogne Portland.	Neat	2,847.	2,597.
	Cement 1, sand 1.70	2,804.	1,038.
	" 1, " 2.55	1,454.	976.
	" 1, " 3.40	931.	747.
	" 1, " 5.00	519.	259.
Rosendale.	Neat, 1	727.3	104.7
	" 1, sand 1.20	310.9	52.4
	" 1, " 1.80	116.4	61.7
	" 1, " 2.35	156.0	
	" 1, " 3.50	52.0	

English Portland Cement. Prisms, 2¼ × 4¼ × 9 inches, on end. Results in lbs. per sq. inch.

Cement.	Sand.	Age, 3 months.	Age, 6 months.	Age, 9 months.
1	0	5806	5388	5974
1	1	2518	3455	4598
1	2	1991	2752	3031
1	3	1406	2167	2401
1	4	1347	1816	2226
1	5	933	1523	1698

The ratio of the crushing to the tensile strength of Portland cement increases rapidly with the addition of sand.

It is thought that the results of the above experiments bear with undue severity on the Rosendale cements. Although these cements frequently show discrepancies in strength there is doubtless little difficulty in finding grades that are much superior to the above; we think such will resist, neat, a tensile strain of not less than 75 lbs. per sq. inch when seven days old. This natural liability to imperfection plainly indicates the necessity of careful testing.

Portland cement, on the contrary, is easily made and preserved of the standard quality, which it has very generally been found to possess in the market.

Curves representing the progress of induration have a parabolic form which is much more regular and apparent for Portland than for Rosendale cements.

General Gillmore experimented upon the adhesion of Rosendale cement to bricks by cementing them together in pairs face to face (flat), and finally separating them by a direct pull. With neat cement, at the age of 320 days, the bricks generally gave way, but with mixtures of sand the fracture occurred in the joint. The following tests where similarly conducted, except that the age was but twenty-nine days, and the pieces were wetted on alternate days.

	Bricks.	*Fine cut Granite.*
Neat cement	30.8 lbs. per sq. in.	27.5 lbs. per sq. in.
Cement 1, sand 1	15.7 " " "	20.8 " " "
" 1, " 2	12.3 " " "	12.6 " " "
" 1, " 3	6.8 " " "	9.2 " " "
" 1, " 4	5.2 " " "	7.9 " " "

It is desirable that the strength and durability of mortar should be quite equal to those of the other materials in a given piece of masonry or concrete, being exposed alike to causes of disintegration. The figures we have given show that the natural cements are not to be relied on, always, as to strength, while Portland cement closely approximates, in this respect as in others, to the better building stones. In removing heavy courses of granite headers and stretchers cut and laid in Rosendale cement in the best manner the writer has, however, seen the beds of the stones partially scaled off, by the adhesion of the mortar, to such an extent as to require re-cutting. This result was doubtless favored by the manner of prying up the stones, and the excellence of the pointing.

Frost gradually disintegrates the surface of exposed Rosendale cement work, though some specimens have been observed to resist it well. Mortar of good Portland cement, after several years exposure to an annual range of temperature from —10° to + 90°, shows not the slightest change of surface.

The tensile strength of Portland cement, mixed to a stiff paste with or without sand, seven days old, is from four to six times greater than that of Rosendale cement similarly treated; but when both are mixed with much water the former may be twenty times stronger than the latter.

CONCRETE.

In recent years the advancement made towards the perfection and cheap production of cements and machinery, has been such that old mixtures and methods will seldom be resorted to in making concrete.

Good concretes must contain mixed sizes of aggregates, disposed, as are the sands in good mortars, in such manner as to produce maximum compactness, and thus require but a minimum of the more costly cementing element. The materials depended upon are enumerated in the general description of concrete heretofore given. Silicious sand hard pebbles, and any hard variety of stone (granite, limestone, etc.), broken to a suitable size, are best; these can generally be obtained in quantities bearing some desirable proportion to each other, and are usually employed in important work, but sometimes the dearth of coarse ballast necessitates the use of sands alone. All these materials should be perfectly clean, otherwise they should be washed in running water, the surf of the sea shore, or by mechanical means. It may occasionally be more economical to increase the proportion of cement in such cases, if it be done intelligently with proper tests. The presence of clay, vegetable mould or "dirt" of any kind is a potent cause of failure, destroying the binding effect of the cement, and hence the coherency of the mass.

Broken stone should be chosen of irregular fracture, not liable to break into flat spawls, nor to give off much dust; the latter should be screened out. Blake's stone-

breaker is the machine at present generally employed for the reduction of the stone. The sizes of the broken stone should be mixed from 1 to 3 inches diameter, governed by the sizes of the other materials at hand.

It is desirable that all the ballast should be hard enough to resist shattering, or even cracking, in ramming.

When the materials are assembled, the next step is to ascertain the voids or interstitial space in each material, by which the best proportions for mixing are indicated, the calculation of space to be occupied by mortar being finally checked by measuring the voids in the proposed mixture. By experimenting in this way considerable nicety of proportion may be arrived at when desired. As previously explained for sand, the voids are readily found by filling a yard measure with the dry material, well shaken down, and measuring the quantity of water it will then hold. Account should always be made of any large quantity of sand contained in the ballast.

In broken stone, of pieces varying from 1¼ to 3 in. diameter and of all shapes the voids are	.50 per cent.
In pebbles of mixed medium sizes	.28 " "
In coarse sand of nearly even grain	.37 " "
In broken stone 1 part, pebbles 1 part mixed	.31 " "

By good proportions the voids of a mixture may be reduced to 22 or 25 per cent.

In proportioning ingredients regard should always be paid to the rule that the quantity of smaller particles, which go to fill up the voids in the next larger size, should always be in excess by an amount determined by the facilities for thorough incorporation; any greater excess being then a question of economy in each case. The bulk of rammed concrete should always be materially greater than that of the contained coarser ballast.

The state of humidity of both atmosphere and ballast affect the quantity required to produce a desired consistency. Workmen must be watched at this point to prevent the indiscriminate use of sun-dried and rain-soaked materials.

Of the many methods of mixing, but one by hand and two or three by machinery are prominent. The first, now practiced only where the limited extent of work will not warrant the expense of a machine, is best performed by four men with shovels upon a platform about 10 ft. square, thus:—

The intended measure of sand for a batch, say 2 barrels, is spread upon the platform and covered by the dry cement, 1 barrel. The whole is then thoroughly stirred by a skilfull use of the shovels, and formed into a shallow basin, into which is thrown most of the water required for the batch, the balance being added later as needed to facilitate the mixing. The mass is again thoroughly turned and mixed until a homogeneous paste is produced; thinly spread out; evenly strewn with the whole proportion of pebbles, say 4 barrels; turned again; again spread out; the quota of broken stone, say 5 barrels, thrown on; and the mixing completed by a thorough turning and re-turning of the whole mass. This is accomplished by opening successive furrows by shovelfuls, instead of continuously like a plow, from two opposite sides to the middle, and then back again. Two such turnings for each of the three additions of material will ordinarily suffice, occupying in all about 30 minutes. To take advantage of a quick-setting cement this time should be shortened by employing more men upon smaller batches. With slow cements the mixing may be more thorough.

The batch assumed is a common one for an ordinary quality of concrete with Rosendale cement, upon large works, and will make rather more than a cubic yard, rammed, depending upon the shapes and sizes of the ballast.

On works of sufficient magnitude the employment of machinery, in the various steps of preparing, manipulating and transporting the materials, saves time and cement, and renders a thorough trituration and incorporation of elements certain and uniform in every batch. Mixing by hand is exceedingly laborious and consequently liable to be imperfect towards the close of a day's work, while the tireless machine still performs its certain round. Existing machinery not only turns out concrete much faster than will a practicable amount of hand labor, but it makes possible, by most intimate and homogeneous mixture, the use of the minimum quantity of cement necessary to completely coat each particle of the aggregates. Mixing machines have been in use for many years in Europe and lately in this country. An early design that served its purpose well, consisted of an iron cylinder—the shell of an old steam boiler, for example—open at both ends and rotating slowly on an axis inclined a few degrees to the horizon. The materials in suitable proportion were constantly fed into the upper end, to fall in due time, well mixed, from the lower end. Of the various devices that have been tried we will describe but one, which has been adopted quite generally on our government works, and which seems to combine most of the elements of perfection. It consists essentially of a very strong cubical box about four feet square, of iron or wood, through two corners of which runs diagonally a stout shaft, firmly secured to the box by cast iron hubs. The shaft rests in bearings, rigidly supported on standards or otherwise, and carries at one end a pulley, spur, or worm gear, preferably the latter, by which a rotary motion is imparted to the box from a steam engine. The cost of such a mixer is from $200 to $300.

In a corner of the box is a trap door through which it is charged from a platform above, and discharged from below, after the mixing is completed by a suitable number of revolutions. The severest wear, in the interior of this mixer, occurs upon an area, about two feet in diameter, in the middle of each side, and around the trap; these parts should be protected, in a wooden box, by thin sheet iron.

(To be continued.)

CORRESPONDENCE.

KANSAS CITY, MO., *March 5, 1877.*

Editor ENGINEERING NEWS:

SIR.—I have examined my question page 27, No. 4 of ENGINEERING NEWS, and fail to see how "C. R.," page 57 of No. 9, can understand it as ascribing pressure to the escaping gases. It will be readily understood that quantities used in such a question must be merely illustrative, the real ones depending on and changing with every variation of either theoretical or practical data. The change from heat to work is not the question, that is generally understood—is written in books—the loss in question is loss of temperature resulting from this change, the gain hoped for, the utilization of more heat from the escaping gases of combustion for the same purpose. Seeing that the question is entirely misapprehended by "C. R.," and hoping that this may serve to make the point aimed at clearer, and invite attention to a subject which is certainly important, induces me to make this rejoinder. G. W. P.

FORT WAYNE, IND., *March 3, 1877.*

Editor ENGINEERING NEWS:

SIR.—As your correspondent Mr. L. L. Nichols, refers to a communication upon the subject of sewers by Mr. E. C. Clarke, which I have not seen, it may be thought that I should allow him to reply; he might not, however, and as a communication from me upon the same subject was published in the NEWS of January 13th, 1877, I wish to notice briefly Mr. Nichols' letter. I have not the benefit of reference to Mr. Kirkwood's book, having only some written notes, but I recollect that the formula $D = \left\{ \frac{m^2}{1450\ S} \right\}^{\frac{1}{5}}$ was based on half a cubit foot, nearly of rainfall, per second, per acre, reaching the sewers; this half cubit foot, nearly, was also based on certain proportions of a rainfall of one inch per hour, reaching the sewers from the street, the house-tops and the yards, within the hour; and as the factor n representing the acreage is a little more than double the factor m representing the cubic feet thus ascertained, and as both vary in the same proportion, he gives the formulæ

$D = \left\{ \frac{m^2}{1450 \times S} \right\}^{\frac{1}{5}}$ and $D = \left\{ \frac{n^2}{5804\ S} \right\}^{\frac{1}{5}}$ consequently $\left\{ \frac{n^2}{5804 \times S} \right\}^{\frac{1}{5}} = \left\{ \frac{m^2}{1450 \times S} \right\}^{\frac{1}{5}}$

I may add that Prony's formula, as quoted by Mr Kirkwood, gives 17 cubic feet instead of 8.56 as stated by Mr. Nichols: for example, $38.08 \times 2.16' \sqrt{2.16 \times S} = 17$ nearly; and according to the modification of the formula, using the fifth root the acreage is 34; using the sixth root, however, the result in cubic feet is 25 and the acreage 50 nearly. JOHN RYALL, C. C. E.

BOSTON, MASS., *March 5, 1877.*

Editor ENGINEEEING NEWS:

SIR.—It may not be uninteresting to you to know that large beds of chalk have been discovered in Kansas within two or three years. They are located about three hundred miles west of Kansas City. It is soft and fine grained, white or slightly yellow, from the presence of oxide of iron. So far as it has been examined, there are no traces of the Rhizopod shells which compose so great a part of the European chalk. Following is an analysis of two samples. No. 1 was pure white. No. 2 was yellowish, and a sample of the poorest:

	No. 1.	No. 2.
Moisture	.34	.58
Insoluble in acids (silica, lime, and alumina)	.69	11.40
Alumina (little oxide of iron)	.43	.97
Ferrous carbonate	.14	2.83
Calcium carbonate	98.47	84.19
	100.07	99.97

The special importance of this is in its applicability to the manufacture of Portland cement. With this chalk, and the clay found also in Kansas, a Portland cement can be manufactured equal in quality to the imported, at a cost of ten to twenty per cent. less. There is a good chance for some man's surplus capital in commencing its manufacture.

I have attended one or two meetings of the Boston Society of Civil Engineers, which were very interesting. The last one was devoted mostly to a discussion of the Ashtabula bridge. The City Engineer of Newport gave a short description of sewerage works established by him at Lenox. An article from him would be interesting. The sewage is disposed of on the Croydon plan. E. B. N.

THE CONVERSAZIONE OF THE MINING ENGINEERS.

NEW YORK, *March 2d., 1877.*

Editor ENGINEERING NEWS:

SIR.—The scientific men of the city and vicinity have been greatly interested in the meetings of the Institute of Mining Engineers, held during the last week in the rooms of the American Society of Civil Engineers, and yesterday was to be marked with a white stone in the annals of the society. After listening to topics of interest, the members, bachelors and benedicts, were treated to a new sensation, namely, that of making the acquaintance of a most useful article, a cradle. There be many bachelors in the number, but they are daily growing fewer. For though an engineer is generally expected to "live under his hat" yet, strange as it seems, they most always succeed in persuading some confiding woman to share their vicissitudes. But of the "cradle," it was'nt, after all, that article advertised as "indispensable in every house," but a mighty one, as well it should be, to rock Science in it on the slender wires of the East River Bridge. Those who made the trip seemed highly pleased, and those who did'nt seemed well *satisfied*, to say the least. Last evening the kindness and forethought of Mr. Edward Cooper had arranged a reception to the members of both Civil and Mining Engineers' Organizations, and the invitations were quite generally accepted. The house was well suited in arrangement for the reception of the guests and Mr. C's care for their wants while there was equally salutary and satisfying. Probably no class of scientific men so delight to unbend from the severe duties of active life and spend a social evening in the lighter duties of a social concourse as do engineers; and the higher the rank attained the more do they seem to prize this unwonted freedom. To the truth of this bear witness the many snow-capped heads which last evening congregated under Mr. Cooper's roof. The fathers of the profession they were, some, whose sons are now illustrious—to follow the thought of the classical writer. Among the more prominent might be noted, the genial Mr. Worthen, without whose pleasant smile no convention or convocation seems complete; Squire Whipple, whose bridges are, as they have been for years, the never-failing source of instruction to the student, and his theme for the great work of his life, viz., his graduating thesis; Mr. Coryell, of Pennsylvania, whose name is synonymous with coal-mining enterprise, and has been for a quarter of a century or more; Col. Milnor Roberts, of canal fame, and whose early recollections of Pittsburgh were a source of delight to the convention held there; and many others well known to "fame and story." The army was also well represented by Gen'ls Gillmore and Barnard, Capt. Raymond, of the Engineers and Lieut. —— of the Ordnance Corps. The press was not forgotten, as the pleasant face of Mr. Rothwell of the *Engineering and Mining Journal* would testify. While members from the west and south, Colorado and Louisiana showed their interest by the long journey they had taken. Engineers being non-partizan politicians, no returning board appeared; matters seemed to be reversed, for it was the engineers who returned, and attacked the board, which was thoroughly fortified against all assaults and withstood them manfully. (Mem. Engineers can be relied upon to eat more and faster than any other profession). Mr. Cooper probably knew this idiosyncrasy, and was well prepared for it. In noting the reception, none should forget the hostess and Miss Cooper, who graced the occasion and well supported the master of house in his successful efforts for his guests' pleasure. The venerable Mr. Peter Cooper, whose name is always identified with anything for the good of his fellows, was present, and to whom nothing scientific is believed to be foreign. During the evening he related to several the history of the first engine on the B. & O. Railroad, and of the inception of the Cooper Union. The latter, it might be remarked, is as noble a monument to the memory of a man as heart could desire.

During the evening the Metric System received its due share of attention, and Mr. Worthen showed that nature endorsed it, as illustrated by the digital and pedal members of the body, although at the same time he deprecated the impending change in the Scriptural passage to "No man lighteth a candle and putteth it under a hectolitre." The thought of the many weary hours engineers have spent and will spend in the perusal of the sacred volume, so agitated the writer, that it or *something else* kept him from his nocturnal rest, and being sleepy he withdraws to needed repose, ranking Mr. Cooper's entertainment with those of Mr. Rogers, of Philadelphia, and Mr. Fink, of Louisiville, long to be remembered, and enjoyed in the recollection.

ALPHA.

THE AMERICAN SYSTEM OF LEVEL NOTES.

ANN ARBOR, MICH., *March, 1877.*

Editor ENGINEERING NEWS:

SIR.—I had no thought of replying to your correspondent in the paper of Feb. 3, when he urged the advantage of the style of level notes there set forth, but when I read the endorsement of your Canadian correspondent in the issue for Feb. 24, I felt moved to come to the defence of what I consider the American system. I hold that the less figures one is obliged to make, the less liability there is for error, and the less one is *obliged* to do in the field, if desirous sometimes of economizing time, the fewer the mistakes will probably be. I am not to be understood as advocating mental calculations, to save apparent figures on the pages of a book, but I decidedly prefer that method which requires the least number of simple operations, with a proper check on the accuracy of the work. While I am aware that it is hard to induce one to change the routine methods to which he is accustomed, I am perfectly willing to leave the merit of the notes submitted here to be decided upon by anyone who will give them a fair trial.

The way in which I have been accustomed to keep

level notes is shown in the table below, and is the method given in Henck's Field Book. After the instrument is placed in position the first sight is a + sight

LEVEL NOTES.

Station.	+ Sight.	Ht. of Inst.	— Sight.	Elevation.
B M.	2.619			106.287
24+60		108.906	3.24	105.67
25			5.12	103.79
26			4.78	104.13
27			5.09	103.82
+20			5.90	103.01
28			6.38	102.53
+40			8.27	100.64
29 t. p.	0.364		7.695	131.211
+60		101.575	8.79	92.78
+80			10.20	91.37
30 t. p.	0.298		9.873	91.702
+25		92.000	4.62	87.38
×60			6.28	85.72
31 t. p.			9.237	82.763
	3.281		26.805	23.524
			3.281	
			23.524	

and all the other are — sights, until the instrument is moved; therefore no further attention need be paid to + or —, to rise or fall of ground. The back sight is placed opposite the point on which it was taken, and the "height of instrument" opposite the first station which it concerns. It appears to me as easy to subtract the minus sight from its "height of instrument" as from the number just above, and, when done, I have the desired elevation, in place of a rise or fall which I must add to or subtract from the preceding elevation. And in the latter case I must note whether it is a rise or fall. Herein the *American* method has a decided advantage, that one need not attend to such a point at all.

For a check:—As shown by the footings, add up the plus sights, add up those minus sights which were the last of each series, or which precede each instrument height. (Here the numbers are easily distinguished by having three decimal places; otherwise they may be set in another column, or they may be underscored or checked.) The difference between these two sums will equal the difference between the first and last elevation. As each elevation, except those taken as *turning points*, is independent of the others, and does not affect others, an error in one of the intermediate elevations is not carried through every following one until a check is applied, perhaps to the bottom of the page, as was done in the table of the first correspondent, when an amount of correcting sufficient to disgust one with *rise* and *fall* must be gone through with.

Further, my practice has been, after subtracting the minus sight from height of "instrument," to mentally add the minus sight to the elevation just obtained, as a check, and it can be done almost instantly. If, at any other time, I desire to look over the notes, I run them over by addition, and can go down the page quite rapidly. If the level rod must be read by the rod-man, he should keep notes himself of all readings which affect the general results, as those are the ones which are taken at the greatest distance from the instrument and are most liable to be heard indistinctly. The rod-man's note book for the above table will look as follows:—

CHECK NOTES.

Station.	+Sight.	Ht. of Inst.	—Sight.	Elevation.
B. M.	2.619			106.287
29 t. p.	0.364	108.906	7.695	101.211
30 t. p.	0.298	101.575	9.873	91.702
30 t. p.		92.000	9.237	82.763
	3.281		26.805	25,524

It will be seen that the check is even more easily applied here. I have sometimes required the rod-man to keep a complete duplicate book. If he is at all bright, he can bring his figures up while the leveller is setting up anew. If now the leveller and rod-man compare the last important reading, bench-mark, height of instrument, or elevation, each time that they pass one another, errors which affect any but a single intermediate station can be at once detected. I have pursued this method, found no trouble, made no delay, and kept everything moving. The intermediates may be looked over again at any time, and no running or cumulative error can ever exist. Of course no notes, however carefully kept, will detect a wrong rod reading. If time is lacking, the intermediate elevations need not be carried out till later.

I am afraid, Mr. Editor, of tresspassing too much upon your valuable space, but, as I am upon the subject, I feel inclined to throw out one or two more suggestions. It is convenient, when reading off, to make a profile, to have no elevations in the elevation column except those which are to go upon the profile; hence I have been in the habit of putting the height of bench marks and of turning points other than stations in the next column to the right. Also, as it is desirable to have the final minus and the previous back or plus sight at equal distances from the level, in order to eliminate an instrumental error, and as this cannot always be done on rough ground, but the distances can be balanced in the long run, when the final result is the same as if they had been balanced all along, I used to make a mark in the station column to denote the location of the level, and thus see that a long plus sight at one time should be compensated for by a similar minus sight later, or *vice versa*. Thus if the level is between 27 and 28, make a mark between those numbers showing its relative position, when you can always afterwards recall that you were 150 ft., 175 ft., etc., from 29, and perhaps 265 ft. or 300 ft. from the bench mark, and you can restore the balance of distance at the first convenient opportunity.

I read with pleasure your letters from correspondents, and hope they will be still more moved to give us some notes from their experience. If any typographical errors creep into the above tables, they must not be laid to the *American system*.

J. B. DAVIS.

SPECIFICATIONS AND BIDS OF WESTERN AVENUE IMPROVEMENT, ALBANY, NEW YORK.

GENERAL DESCRIPTION.

On that portion of Western avenue, included in this agreement, the roadway and sidewalks are to be constructed, the curbs set and gutters laid, the labor and materials furnished as is hereinafter more particularly described, all in accordance with the plans and specifications as prepared by the Engineer of the Board of Commissioners of Washington Park.

All material furnished, and all the work done, which, in the opinion of the Committee on "Roads, Avenues and Grading," of said Board of Commissioners of Washington Park, or of their authorized agent, shall not be in accordance with these specifications or plans, shall be removed and other materials furnished and work done that will, in the opinion of the said Committee or their authorized agent, be in accordance therewith.

The sand for the roadway, cross-walks, curb and flag sidewalks shall be of yellow sand similar in character and equal in quality to that used in paving Madison avenue, and shall be free from roots, loam or vegetable matter.

The sand shall be placed upon the road-bed in two successive layers, each six inches in thickness (but only where the road-bed has been brought to the proper subgrade), and each layer shall be well rolled until it is firm and compact. Upon this, when thus compacted, four inches of clean, sharp, black sand, free from roots or large stones, shall be placed, by hand or with barrows from the sidewalk lines, but not by means of carts or wagons.

The curb shall be of the best quality of blue stone. They are to be in lengths of not less than three feet, to be not less than four inches in thickness for the full depth of the stone, and shall be not less than twenty inches in depth the entire length of the stone. The top of the stone shall be cut to a bevel with the front, the front to be cut smooth and to a fair line, without rounding, and with no projection or depression exceeding one-quarter of an inch from the working line to a depth of ten inches from the top. The bottom to be roughed off, parallel to the top, to the full thickness of the stone. The ends from top to bottom shall be truly squared and dressed so that when laid and abutted, the one against the other, the joints shall not exceed three-eighths of an inch in width. All curb shall be hammer-dressed to depths and lines shown on plans.

The hammer-dressing for curb as above specified is that between quarry dressed and fine axed.

The curb for corners shall be of dimensions shown on the plans. They shall be cut to the radii shown, and shall lay to the same thickness of joint as provided for the straight curb. In all other respects they shall be dressed as specified for the straight curb, and shall be of the same quality and character of stone. The length to be paid for such circular curb shall be that measured on the exterior curve of the stone. The curb, both straight and circular, shall be as nearly as possible of uniform color. Where special lengths of either straight or curved curb shall be required, they shall be furnished and paid for at the price paid for ordinary straight or curved curb.

All curb shall be laid truly to the lines and grades, and shall be driven to a firm and unyielding bearing by means of a wooden pounder of not less than 50 pounds weight. The joints between abutting curb shall not exceed three-eighths of an inch in width. The curb shall be backed up with at least one foot of clean sand, which shall be well rammed. All curb shall be set so as to show the front to the depth shown on plan. If, after being set, any curb should break or settle below the finished grade line, such curb, if unbroken, shall be reset—if broken, a new one shall be put in its place without extra cost.

The gutter stone shall be of granite, similar in character and quality to that used for the street pavement, and shall be of the following dimensions: "Not less than three nor more than four feet in length, not less than six nor more than eight inches in depth, and not less than twelve nor more than fifteen inches in width."

They shall be dressed to an even face on the top and bottom, the sides and ends shall be square and full, and be cut so as to lay to a joint not to exceed three-eighths of an inch in width from top to bottom.

The stone shall be well and firmly bedded in the sand provided for the pavement, and shall be driven to their beds by means of a wooden rammer, as provided for the setting of the curb. The stones are to be laid in alternate widths of twelve and fifteen inches respectively, as shown on plans.

All flag shall be of the best quality of blue stone, free from cracks or shakes, not less than three inches in thickness—six feet in length, by from three to four feet in width. They shall be as nearly as possible of uniform color. They shall be smooth and even on the upper surface, the sides dressed clear of drill or chisel holes, and square with the upper surface for at least one inch down. The edges where they abut to be so dressed as to make joints not exceeding one-half of an inch in width.

The stone shall be bedded in eight inches of yellow sand, similar in character and quality to that used for the roadway. They shall be laid truly to the lines and grades given, with close joints, not exceeding half an inch in width, with a true and level surface, the joints to be filled with clean, sharp, black sand, and swept clean on the surface. If any flag shall break within one month after completion of the work, or during the progress of the work, owing to the deficiency of the foundation or imperfect bedding, or through the carelessness of the party or parties to the contract, or of those in his or their employ, such flag stone shall be replaced by a perfect stone, without extra cost.

The stone for the pavement, wheelway or roadway, shall be of granite, of the following dimensions:

"From (3½) three and one-half inches to (4½) four and one-half inches across their upper and lower faces; from seven (7) to eight (8) inches deep, and from (10) ten to (14) fourteen inches in length; but in no case shall they be less than (8) eight inches nor more than (14) fourteen inches in length." The granite of which these stones shall be made must be equal in hardness to Quincy granite, or to that from the quarries of the Pigeon Hill Granite Company.

They shall be laid with their longest dimension at right angles to the center line or axis of the avenue as far as the gutter stone of the avenue; but on streets intersecting Western avenue, they shall be laid with their longest dimension parallel with the center line or axis of the avenue, from the curb line of Western avenue as far as the cross-walk stones, as shown on plan.

They shall break joints in alternate courses, each course of blocks as far as practicable to be of uniform width and depth, and so laid that all longitudinal joints shall be broken by a lap of at least three inches.

They shall be well bedded in the sand provided, and after bedding be rammed with a pounder weighing at least 50 pounds. Their surfaces shall then be covered with a thin layer of clean, sharp, black sand, which shall be thoroughly brushed in to fill up the joints, and they shall again be rammed until there shall be no settlement of any stone below the finished cross-section established.

In case of settlement below such finished cross-section, the stone shall be lifted and reset, and again rammed until they form and set to such finished cross-section.

The joints between the stones shall in no case exceed one half of an inch in width, and the pavement shall, after being thus firmly rammed, be covered with not less than one inch of clean, sharp, black sand, from which the larger stone shall have been removed by screening.

It is particularly specified that the stone shall be as nearly as possible square on all their faces, and that the joints when laid shall not exceed one half of an inch in width, and that no portion of the pavement shall be estimated upon or accepted where the joints between the stones are in excess of the dimensions above specified.

A. The crosswalk stone shall be similar in character and quality to that used for the roadway, and shall be not less than four feet in length, two feet in width, and no less than six inches nor more than eight inches in thickness throughout. They shall be dressed to an even face on top and bottom. The sides and ends shall be square and full, and be cut so as to lie to a joint not to exceed three eighths of an inch from top to bottom.

The stone shall be well and firmly bedded in the manner provided for the stone pavement, on a foundation of yellow sand, similar to that specified for the pavement, and laid with joints as above specified.

The courses are to be laid so as to break joints, and to be separated by two rows of granite blocks similar to those used in the pavement.

N. B.—Bids will also be received for the furnishing of "Belgian" cross-walk stone of sizes specified in A, but parties making proposals for furnishing all the materials and labor under section I of Proposals, must state in such proposals the character and quality of the stone they bid upon, whether it is Belgian or granite cross-walk stone.

The whole of the material to be furnished and all the work to be done under these specifications and plans shall be at all times subject to the inspection and approval of the "Board of Commissioners of Washington Park of the city of Albany," and any material furnished or work done which shall not conform to these specifications or plans, shall be removed or taken up by the contractor or the parties to the contract, at his or their own cost, and other material or work furnished and done which shall be satisfactory.

As the work progresses toward completion the party or parties to the contract shall, from time to time as the engineer directs, clear away and remove from the limits of the avenue all earth, sand, stone, refuse or surplus material of every description, and the avenue shall be left in every respect in clean and orderly condition. Until this has been done, no portion of the work shall be considered as completed.

Work shall be commenced at such time and at such points as the Board of Commissioners of Washington

Park may direct. The work shall be completed in all its parts by the 1st day of October, 1877.

The Board of Commissioners of Washington Park shall be held blameless for any damage to person or property arising from neglect on the part of the contractor or those in his employ.

The following are approximate quantities of material:

Paving—37,408 square yards.
Straight Curb—15,296 linear feet.
Circular Curb—550 linear feet.
Flag—93,828 square feet.
Gutter Stone—16,825 square feet.
Crosswalk Stone—1,130 square yards.
Yellow Sand—18,000 cubic yards.
Black Sand or fine Gravel—6,386 cubic yards.

An aggregate bid for the entire work, including material and labor, will be received.

Also bids for the material and labor, each separate, as follows:

1. For the Grarite.
2. For Stone for curbing and flagging.
3. For all the labor, including sand.

Bids were made under the proposals in two ways: 1. For the entire work complete, including labor and material; and 2. For material and labor separate. The grading is already completed.

There were thirty-four bidders, under one or the other of these heads. They are subjoined as tabulated:

AGGREGATE BIDS FOR ENTIRE WORK.

Sweet, Feeley & Co., Albany	$173,397.40
Patrick McQuade, Albany	144,876.00
John Casey, Albany	154,000.00
Thomas Riley, Albany	136,000.00
James McDonald, Albany	168,000.00
Charles Guidet, New York	189,565 59
Sherman, Flagler & Co., Troy	176,900.00
Stephen B. Trull, Cohoes	134,754.03
John Smith, New York	145,000.00
John McKim, New York	140,000.00
John R. Briggs, Massachusetts	160,000.00
Robert Harrop, Albany	136,627.84
John McDermot, Albany	177,442.25
Wm. Casey, Albany	153,000.00
Jacob Holler, Albany	155,500.00
James Boyle, New York	144,737.00
John Ryan, Albany	138,000.00
Thomas Tawley, New York	151,500.00
Thomas McCann, Brooklyn	139,000.00
McConnel & Jones, Rochester	190,000.00
Geo. Martin & P. Farley, Albany	139,000.00
Alexander Kennedy, Albany	139,975.00
John H. Finn, Albany	141,700.00
F. B. McCarthy, Albany	178,000.00
Edward Grimes, Albany	156,500.00
Patrick Hanlon, Brooklyn	130,303.66

A deduction of $2,000 from all of the above bids is to be made if Belgian stone is used for crosswalks.

SPECIAL BIDS.

John Casey—Sand and labor	$ 25,025.67
Blue stone	25,579.38
Granite	107,405.05
Total	$158,011.60
Jas. H. Y. McDonald—Blue stone	$22,158.20
Spec. bid for Belg. crosswalk	2 847.60
Thos. Riley—Sand and labor	$30,320.53
Blue stone	20,252.66
granite	83,097.60
Total	$133 670.79
Spec. for Belg. crosswalk	2,919.30
McMurray & Weidman—Granite	$95,474.50
John Flagler—Blue stone	$26,581.86
John McKim—Sand and labor	$24,670.11
Blue stone	22,607.12
Granite	83,840.90
Total	$131,118.13
Spec. bid for Belg. crosswalk	2,919.30
Chs. F. North—Blue stone	$24,146.24
Jacob Holler—Sand and labor	$ 26,008.43
Blue stone	25,341.69
Granite	106,2;9.70
Total	$157,629.82
Spec. bid for Belg. crosswalk	2,938.00
John Ryan—Blue stone	$21,029.50
Spec. bid for Belg. crosswalk	2,542.50
Geo. Martin & P. Farley—Sand and labor	$22,133.12
Blue stone	24,493.94
Granite	94,919.05
Total	$141,546.11
John H. Finn—Sand and labor	$25,479.09
Bigelow Blue Stone Co—Blue stone	$25,810.83
Spec. bid for Belg. crosswalk	3,356.10
Thos. McCarthy—Sand and labor	$19,873.08

The Commission had these proposals under consideration for several days, and decided to award the contract to Patrick Hanlon, of Brooklyn, the lowest bidder. As proposed his bid was $130,303.66.

By determining to use the paving block instead of gutter stone, and granite instead of Belgian crosswalks, this aggregate was reduced to $127,000—the sum at which the contract will be awarded.

Mr. Hanlon has associated with him Mr. William H. Baird, and the surities offered are ample.

Inquiries have satisfied the Commission in respect to the competency and responsibility of these gentlemen; and it is believed that the work will be promptly and satisfactorily performed.

WILLIAM S. EGERTON, *Engineer.*

TOMPKINSVILLE, N. Y., *March 1, 1877.*

Editor ENGINEERING NEWS:

SIR.—Agreeable to your request of the 22d ult., I have to enclose herewith a list of the bids received at this office on the 26th ult., for the cut stone work of the Stratford Shoals Light-house. A copy of the detail plans and specifications has also been mailed to you this day. Very respectfully

J. C. WOODRUFF,
Colonel of Engineers, U. S. Army.

Abstract of bids for cut stone for Stratford Shoal Light House, received at opening of February 26, 1877, at office of Engineer, 3d Lt. Ho. Dist.:

Name of Bidder.	Place of Business.	Amount Bid.	Samples of Stone.	Remarks.
E. T. Huston	Groton, Conn	$2,559 00	None sent.	Informal bid, wholly so.
M. K. Chase & Co	Bluehill, Me	2,750 00	Very good.	
Pierce, Glover & Co	Granville, Me	3,070 00	" "	
Granville Granite Quarry Co	Granville, Me	3,200 00	" "	
Noland & McGrath	New York	3,249 00	Informal bid.	
Hallowell Granite Co	Hallowell, Me	3,333 00	Very good.	
Smith Granite Co	Westerly, R. I	3,351 86	" "	
Concord Granite Co	Boston, Mass	3,450 00	" "	Certificate.
John S. Hopkins	Vinal Haven, Me	3,495 00	" "	"
John Beattie	Guilford, Conn	3,575 00	None sent.	
Chas. P. Chapman	Westerly, R. I	3,700 00	Very good.	
W. & J. Beattie Jr	Fall River, Mass	3,700 00	" "	
Chas. F. Stoll	New London, Conn	3,073 00	Good.	
D. V. Howell	New York	3,697 57	"	" wholly.
Rodwell Granite Co	Rockland, Me	4,083 00	"	" Certificate.
F. A. Ingerson	New London, Conn	4,140 00	None sent.	
E. Vesecott & Son	North Haven, Me	4,238 00	Good.	
Cape Ann Granite Co	Gloucester, Mass	4,825 66	"	
Bay State Granite Co	Rockport, Mass	4,896 61	"	
Fall River Granite Co	Fall River, Mass	4,980 00	"	
Plummer Granite Quarry	Northbridge, Mass	5,450 00	"	
Rothwell & Co	Washington, D. C	6,987 00	"	bid.
Jas. M. Andrews	Biddeford, Me	7,000 00	"	Certificate.

For Stone Superstructure, Water Works. Lake Crib, Cleveland, Ohio:

Name of Bidder.	Place of Business.	All Lime Stone.	1st, 2d, 3d, Courses Lime Stone, others of Sand Stone.	1st, 2d, 3d Courses Medina Sand Stone, others of Sand Stone.
Farris & Garfield	Painesville, Ohio	$83,465 00	$85,000 00	$89,000 00
Geo. M. Smith	Cleveland, Ohio	77,500 00	75,000 00	77,000 00
A. A. McDonell	Chicago, Ill	53,530 00	54,544 00	57,000 00
E. D. Delamater	Cleveland, Ohio	81,000 00	80,000 00	85,000 00
Geo. S. Hebard	Chicago, Ill	80,674 00	66,670 96	70,000 00
C. H. Strong	Cleveland, Ohio	73,650 00	66,660 00	72,700 00
Jno. E. McMahon	Cleveland, Ohio	76,500 00	69,300 00	75,400 00

Contract awarded to A. A. McDonell. Kind of stone to be used not yet determined.

J. WHITLAW, *Supt. and Engr.*

BOSTON *March 1, 1877.*

Editor ENGINEERING NEWS:

SIR.—I send a statement of the bids received in answer to the advertisement last week. We consider the price very low. The total amount of contract No. 1 is $73,392.00; No. 2 $71,408.00; No. 3 17,582.40.

Yours respectfully,
DEXTER BRACKETT,
Assistant Engineer.

Bids for Cast-iron Water pipes, received March 1st, 1877:

Contract No. 1.	Jesse W. Starr & Sons, Camden, N. J.	R. D. Wood & Co., Philadelphia, Pa.	Gloucester Iron Wrks, Gloucester City, N. J.	McNeals & Archer, Burlington, N. J.	Warren Foundry & Machine Co., Phillipsburg, N. J.	Lake Shore Foundry, Cleveland, O.	Dennis Long & Co., Louisville, Ky.

PONTIAC, MICH, *March 1, 1877.*

Editor ENGINEERING NEWS:

SIR.—In compliance with your request, I forward herewith a synopsis of proposals received and opened yesterday for gas fitting and gas works for the Eastern Asylum,

Some of the bidders made more than one proposal, varying the amounts according to specifications prepared by themselves.

Berry Brothers' proposal for gas fitting was conditioned upon their receiving the contract for gas works also.

The contract for gas fitting was awarded to James McEwan & Co., they being the lowest bidders.

The Board took until their next regular meeting, March 13, to consider proposals for gas works.

C. M. WELLS, *Sup't.*

For Gas Fitting and Gas Works for the Eastern Asylum for the Insane. To supply gas for 970 burners:

James McEwan & C.o, Detroit, Mich., gas fitting, $2,156.00; Detroit Metal and Plumbing Works, Detroit, Mich., gas fitting, $2.198.15; Monat & McDonald, Detroit, Mich., $2,375.00; Waite & Williams, Toledo, O., gas fitting, $2,495.00; Ferguson, McKay & Co., Detroit, Mich., gas fitting, $2,600.00; Holmes & Webster, Detroit, Mich., gas fitting, $2,600.00; W. D. King & Co., Pontiac, Mich., gas fitting, $2,750.00; Berry Brothers, Detroit, Mich., gas fitting, without meter, $2,075.00; Berry Brothers, Detroit, Mich., gas works, $5,000.00, $3,600.00, $4,500.00, $3,000.00; Gilbert & Barker M'f'g Co., Springfield. Mass., gas machine, $4,000.00; Kerr Murray, Fort Wayne, Ind., gas works, $7,650.00. $6,-750.0., $1,450.00, $4,000.00; W. W. Gibbs, Boston, Mass., gas works, $5,900.00; Thomas H. Hicks, London, Ont., gas works, $9,000.00, $6,300.00; J. D. Patton, Hicksville, Ohio, gas works, $10,300.00. Allen A. Ravenaugh, Detroit, Mich., Agent Pontiac Gas Co., proposes to supply gas at $2.50 per thousand feet.

F. E. Walker, Secretary of the School Commission, Bedford, Iowa, informs us that J. C. Woodruff, not signing contract and bond within the ten days allotted him for the building of the School House, the Board awarded the contract to J. W. Combs, of Bedford, for $15,300, on March 6th.

Messrs. H. A. Ramsey & Co. were recently awarded the contract to construct an iron truss bridge over the Baltimore & Potomac Railroad at its intersection with Argyle avenue, Baltimore, for $11,000. The only other bid was by Wendell Bollman, at $12,311. The bridge will be 112 feet long and 60 feet wide, in three spans, with trusses 8 feet deep, a roadway in the centre and two footways on both sides.

REMOVAL OF THE ROCK OBSTRUCTING THE ENTRANCE TO EAGLE HARBOR, LAKE SUPERIOR.*

BY L. W. SCHERMERHORN.

The port of Eagle Harbor is situated on the northwest shore of Keweenaw Point. It is the receiving and shipping port for a large number of copper mines and the only port affording harborage between Portage and Marquette, a distance of about 140 miles. The shores in the vincinity are rocky and bold, dangerous to approach during northerly gales. A rocky escarpment forms the shore line, extending many miles on each side of Eagle Harbor, and in the submerged ledge across the mouth of the Harbor forms the obstruction under consideration.

Geologically the formation belongs to the Silurian, the rock immediately forming the obstruction to the Harbor is *trap* intersected with veins of chlorite and quartzite. The stratification has a dip of 21°, the rock is exceedingly hard, with a close and crystalline texture. The rock forming the bar rises rapidly on the outside from a depth of 30 feet to a depth of about 8 feet on the crest, and again slopes to a depth of 30 feet within the Harbor.

The width of the proposed improvement is 130 feet, and having a depth of at least 14 feet below low water surface of 1868, or about 16 feet below average summer level.

The area covered by work is 32000 square feet, and required the removal of 3000 cubic yards. The work has been done by the United States Government by day's labor.

The following plan was adopted:

1st. Iron tripods resting upon the bottom and giving support to a platform carrying:—

2nd. Steam drills, steam being furnished from a boiler placed on a scow, which when working was moored along side the platform.

3rd. The use of Dynamite as an explosive and the subsequent removal of the rock by dredging:—

The tripods consisted of bars of railroad-iron 25 feet in length, and weighing 19 pounds per linear foot.

In the construction of a tripod, 3 bars were securely chained together near their upper ends, the lower ends being spread apart forming in plan the apexes of an equilateral triangle whose sides were 20 feet, the legs of the tripod being maintained in their spread position by horizontal timbers clamped to the rails. Eight such tripods gave support to the drilling-platform. The tripods were placed 33 feet apart each way. The drilling platform consisted of 12-inch by 12-inch timbers, 36 feet in length. They were slung to the tripods by a ⅝-inch chain. A pair of 12-inch by 12-inch timbers, 36 feet in length, carried the drilling-frame. It consisted of a frame of 3-inch crossed planks, upon which the drills were placed.

The operation of handling the drills was, briefly, as follows:

The tripods and drilling-platform being in position, the pair of 12-inch by 12-inch timbers were laid in place and the drilling-frame placed thereon. The drills were then hoisted by the derrick and steam-hoist from the deck of the scow, and lowered to their place on the drilling-frame.

On the completion of a hole, a light block and fall enabled two men to easily and quickly slide the drilling-frame carrying the drill in position for another hole.

Upon the completion of a row of holes, the pair of 12-inch by 12-inch timbers, with drilling-frame and drills, were in the same manner moved sidewise for a new row of holes. This method obviated the necessity of lifting and moving drills weighing 850 pounds by hand.

On account of the spring caused by the blows of the drills, it was found necessary to support the main timbers at a point midway between the tripods. This was done by a vertical spar or post resting upon the bottom, and attached to the timbers of the platform by a chain and turn-buckle, allowing any desirable part of the weight to be imposed upon the post.

The platform was practically rigid and but little motion observed, even when both drills were running on the same part of the platform.

When the area covered by the platform had been drilled, the chains by which the 12-inch by 12-inch timbers were slung to the tripods were slackened allowing the timbers to fall into the water; by the derrick and steam-hoist, which were placed on the scow, the tripods were placed in their new position, the timbers floated into place, and likewise raised and attached.

It was not usual to interrupt drilling during the removal of the platform, since two or more tripods could be moved as soon as the area under that part of the platform had been drilled. The upper surface of the platform was about 4 feet above the water. It would be proper to add here that the platform could not be maintained intact during the heaviest northerly gales, at which times it, including the tripods, was overthrown, the loosened timbers being driven inside the harbor, where they were easily regained; the entire overthrow of the platform seldom delaying possible drilling more than ten hours. In two cases tripods without any attached platform were overthrown. The drills used were the "Improved Ingersoll," and of the size known as 5-inch, (referring to diameter of steam-cylinder); each drill weighs, with tripod, 850 pounds.

The drill-steels consisted of octagonal steel, 1¼ inches and 1¼ inches in diameter, of the length of 10 feet, 13 feet. 16 feet, 19 feet, 21 feet and 23 feet.

The size of the bitts was 3 inches, 2 and ¼ inches, 2½ inches, and 2¼ inches in diameter. The holes were begun with the largest sized bitt belonging to the length of steel required, reducing with successive steels. This was necessary on account of the wearing of bitts, producing thereby a hole gradually lessening in diameter.

As is so frequently the case the real difficulties arose from apparently insignificant causes—in this case it came from the gravel and boulders covering the surface of the rock, for a depth of from 1 to 2 feet—without some means of protecting the holes drilled, from this gravel the work would have been idle, for unless guarded against the pebbles would fall in the hole above and around the bitt and either preventing the withdrawal of the bitt, or immediately filling the hole when withdrawn.

After many experiences the following device was used with perfect success. It consisted of a cast-iron disc, 15 inches in diameter, with low legs, and having a weight of about 150 pounds. Through a hole in its center passed an iron pipe 4½ inches exterior diameter, and prevented from withdrawing through the casting by an enlargement at lower end; the pipe was about ½ an inch smaller than the hole through casting, thereby allowing considerable adjustment between the two, in the final position taken by the casting on the bottom. By ears attached to the upper end of the pipe light ropes were carried up to the drilling platform; its operation was as follows: After the adjustment of the drilling steel, and before starting the hole, the pipe and attached casting was lowered over the head of the steel and allowed with slackened ropes to rest upon the bottom. The early blows of the steel knocked aside the boulders and gravel allowing the pipe to follow down to the rock. The early blows of the drill produced a hole at starting something larger than the cutting edge of the bitt thereby allowing the pipe to enter a short distance into the rock and perfectly excluding the drift from the hole. The feed of the drills was 3 feet, after which a steel 3 feet longer was introduced. With the introduction of the second steel another pipe, with exterior diameter just sufficient to pass within the pipe attached to casting, was dropped over the second steel passing inside of the larger pipe and into the hole already drilled for a depth of from 1 to 2 feet. Successive steels were introduced until the hole had reached the required depth.

After the withdrawal of the last steel the casting and attached pipe was lifted, by the attached ropes, over the smaller pipe, leaving the latter fixed in the hole. A new hole was started and the process continued until a section was completed—usually 16 holes. These smaller pipes remained in the holes until they were charged and only withdrawn just previously to firing. By this method a hole was rarely lost by filling with gravel. This device had been previously used at Ahnapee, Wis.

The *boiler* furnishing steam to the drills and hoisting-engine was a locomotive boiler, 12 feet in length, 3 feet in diameter, with 30 3-inch flues, and rated at 25-horse power. It furnished with ease all power required. The consumption of fuel was about half a cord per day of half dry soft wood; a pressure of 65 pounds was required for the proper working of the drills; with this pressure from 180 to 250 strokes were given per *minute*. The scow held the boiler, derrick, hoisting-engine, portable forge and anvil, air-pump, and such other tools and supplies as were in immediate use. It was 80 feet long, 16 feet wide, and 5 feet high. It served as a working base in all the operations of the work. Its position during drilling was closely adjacent to the platform, where it was held in smooth weather by lines thereto attached, and in rough weather by a bow anchor permanently placed outside the entrance, a side anchor and a stern line attached to dock. The scow was moved by means of a winch-head attached to the winding shaft of the hoisting-engine, and so arranged as to run either when the winding drum was in motion or at rest. In moving the scow from the dock to platform, a distance of 1,000 feet, the line from the bow-anchor passed around the winch-head, while the stern or dock line was paid out. In returning the operation was reversed. It required about fifteen minutes to move in or out.

The holes were drilled 3 inches in diameter at the top, reducing about ¼ inch each 3 feet in depth. They were drilled to a depth of 16 feet below low-water surface of 1868, being 2 feet below bottom of proposed excavation. The holes were drilled nearly vertical. Oblique holes would have conformed better to the stratification, and given greater lift in blasting; still the spring of the steels and the difficulty of direction and management would more than offset the advantage gained. The character of the rock was such as to make the rate of penetration very irregular; at times it would be as high as 0.5 feet per minute, at others as low as 0.01 foot per minute. This latter rate was due to veins of quartzite and veins of conglomerate; in the latter, small pebbles becoming detached from the sides of the holes, fell in above the bitt, causing a difficulty both in progress and withdrawal. At times small masses of copper entirely stopped the penetration of the drills.

The explosive used was Dynamite, of two qualities, viz., No. 1 and No. 2:

No. 1 containing about 75 per cent. nitro-glycerine.

No. 2 containing about 36 per cent. nitro-glycerine.

The cartridges were of the following dimensions:

No. 1 cartridge, 1¼ inches diameter, 8 inches long; weight, ½ pound.

No. 2 cartridge, 1¼ inches diameter, 8 inches long; weight, 1 pound.

From 6 to 16 holes were fired at once. The detonation was not excessive, and fragments of rock never appeared above the surface.

The firing was done by Mowbray's frictional battery.

The holes were generally placed 7 feet apart each way, and drilled to a depth of from 3 to 4 feet below proposed bottom. They were charged with about 12 1-pound cartridges of No. 2, and from 4 to 6 1-pound cartridges of No. 1. The former were placed in the bottom of the hole, the latter on top; the upper cartridge contained the exploding cap.

The cartridges were introduced into the holes by a diver and rammed well down by a landing pole operated from the platform above.

The scow was usually moved back from 50 to 100 feet from the area exploded. The cartridges were frequently left in the holes 24 hours before firing; a limited action of water did not seem to produce any injurious effects.

The dynamite was handled with due regard to the fact that it was an explosive but with less care probably than would have been used in the case of black powder, from an experience of two years I should prefer—in the matter of safety alone—to use dynamite to black powder.

The exploder used consisted of a copper cap filled with about 25 grains of fulminate of mercury.

The force employed on the work was as follows:

1 overseer, 1 fireman, 1 blacksmith, diver, divers attendant, 2 drill runners, 2 drill helpers, 2 jobbers; in all 11 men. 2 drills were generally kept running; this force was found sufficient except in the rough weather of the fall. The working season is short, since the harbor opens about the last of May; and the fall storms beginning about September 15th, practically close the season; from 3½ to 4 months comprise the possible working season.

The work has been twice let by contract, and each time the contractor has failed to produce practical results.

The first contract for the removal of the rock was let in 1867, for $58 per yard; the second in 1869, for $40 per cubic yard; the work will be accomplished under the present plan for less than $10 per yard.

The following detailed statement of the last years work will be of interest. It is prepared from carefully kept records of the work during the past two years:

Aggregate depth drilled	4044.	ft.
Average " of holes	6.0	"
Aggregate area drilled over	26000.	sq "
Average depth drilled per hour	3.7	"
Average amount No. 1 dynamite per hole	3.0	lbs
" " No. 2 " "	12.0	"
Number of steels sharpened	790.	
Loss of steel by wear and sharpening	91.	lbs.
Average depth drilled per steel sharpened	5.1	ft.
Cost per lineal foot drilled (including labor, steel used, fuel, oil and coal, also labor in erecting and maintaining platform)	$0.70	
Cost per lineal foot drilled and blasted (including labor, steel, fuel, oil, coal exploders and dynamite)	$2.30	

The above does not include investment, or depreciation of tools or machinery. The approximate cost of machinery, tools and supplies used and on hand is $12,000.

Common labor has been paid from 17 to 18 cents per hour, skilled labor from 20 to 25 cents per hour.

33. The true curve of equilibrium for the load uniformly distributed along the rib is a curve which will be *tangent* to the sides of the funicular polygon just drawn. The closer together the points D, E, etc., are taken, the nearer the two will come together. If the points at which the loads are concentrated divide the span into equal portions, that is, if the end distances are the same as the others, so that the portions of load near B and C are concentrated on those joints, the true curve of equilibrium will pass through the *vertices* of the funicular polygon. Such a distribution of load is made in bridge trusses and roofs, when a half panel weight is thrown on each abutment. The curve assumed by a rope or chain, of uniform weight per foot, when suspended between two points is called a *catenary*. Since the curve of equilibrium, in Fig. 6, if we had not placed the extra weight on D, would have come quite near to the rib, this curve would have been a close approximation to a catenary. As we expect to make some use of this curve later, we will show how to draw one at that time.

If the load on this arch were distributed uniformly horizontally, the curve of equilibrium would be a parabola. In case the whole arch were a parabola with the vertex at the crown, and the load extended over the entire span, the two curves coinciding at the springing points and the crown, would be identical throughout, and the rib itself would be in perfect equilibrium.

34. That the parabola is the curve of equilibrium for a continuous load, distributed uniformly horizontally, may be shown as follows :—Let A B, Fig. 7, be a portion of a cord, horizontal at A, which is in equilibrium under such a uniform load, represented by A C. The tension at A will be in the line of the tangent A C; the resultant of the load A C will be vertical and must pass through its middle point D. As the cord A B is in equilibrium under its load and the reactions or tensions of the other portions of the cord at A and B, the tension along the tangent at B must, by § 1, also pass through D.

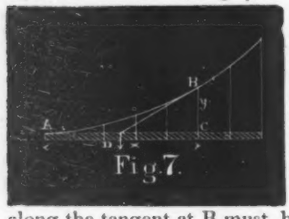

Fig. 7.

As B C, drawn vertically, is parallel to the resultant of the load, the sides of the triangle B C D will be proportional to the three external forces, and, if A C = x, B C = y, W = total load on A B, = $w\,x$, (where w = load per unit of length), and H = tension at A, we have

$$W : H = B C : D C = y : \tfrac{1}{2}x,$$

$$\text{or, } y = \frac{W\,x}{2\,H} = \frac{w}{2\,H}\,x^2,$$

the equation of a parabola with vertex at A.

Therefore an arched rib of parabolic form, when loaded uniformly horizontally, has no tendency to change its shape, or experiences no bending moment, at any point.

35. If the load extends over a portion only of the span of the arch, and is uniformly distributed horizontally, the curve for the loaded portion is parabolic, while that for an unloaded portion will be a straight line ; thus, if the load extends from one abutment to the middle, we shall have, on the unloaded half, a straight line from the abutment to the crown, and, on the loaded half, a parabola from the crown to the springing. As it will be seen from the funicular polygons of Figs. 1 and 2, that any two sides of the funicular polygon, when prolonged, meet on the vertical drawn through the centre of gravity of so much of the weight as is included between these sides, the curves of equilibrium for any cases where the rib is hinged at three points can be drawn without previously determining the value of H. Thus, in the case just supposed, of a load over the half span, from B to F in Fig. 5, the centre of gravity will be at G. Then if G C is the vertical drawn from G the side of the funicular polygon, or, more properly, the tangent to the curve of equilibrium, at B must pass through C, where C G meets A D, and the required parabola will be drawn from D to B on D C and B C as tangents. As one point of the curve we have the middle point of the line from C to the middle of the chord D B. We can then turn round and find H by drawing 1-0 and 2-0, parallel to A C and C B. Henck's "Field Book for Railroad Engineers," gives methods for constructing parabolas, and we shall cite another presently. A handy construction when two tangents are given, as in the present case, may be found in "Graphical Analysis of Bridge Trusses," p. 19, § 10.

36. We would suggest the following examples for practice. Given a semicircular rib, loaded uniformly horizontally over the whole span, and pivoted at the crown and springings ; the maximum bending moment occurs at 30° from the springing and is equal to one-sixteenth of the total load multiplied by the radius of the arch, while H is equal to one-fourth of the total load. Given a parabolic arch similarly pivoted, and in equilibrium under a steady load distributed as above; add a similar travelling load from one abutment to the middle of the span; the maximum bending moment is found at one quarter of the span from either abutment, is of opposite signs at those two places, and is equal to one-thirty-second of the travelling load then on the arch multiplied by the span, while H for the travelling load equals the same quantity divided by one-fourth the rise of the arch, and for the steady load is twice as much.

37. It may be desired, when designing an arch of this type, to find the extent of load which will produce the maximum bending moment at each point, and the value of that moment. Suppose the point N, Fig. 5, to be examined:—Prolong B N until it meets A D at E; it is then manifest that any load in the vertical through E will cause no bending moment at N; that any load on the right of E will have its curve of equilibrium outside of the arch at N, while loads to the left of E will cause the curve of equilibrium to pass inside of N. Therefore the maximum bending moment at N of one kind will be found when all possible loads are put on the arch from B to the vertical through E, and the maximum moment of the other kind occurs when the load extends from A to E. As the arch tends to move away from the curve of equilibrium, the kind of moment is easily distinguished. H can then be found, the curve of equilibrium drawn, the ordinate scaled and multiplied by H.

38. For the reason that the curve of equilibrium is at once definitely located by introducing three hinges or pivots, no matter what form the arch may have, that type which used to be known as the braced arch, with a horizontal upper and a curved lower member, the spandril being filled with bracing, has usually been treated as free to turn at both crown and springings; then a diagram may be drawn by Clerk-Maxwell's method, or the stresses may be found from the curve of equilibrium. While a diagram only gives the stresses in the various members for one position of load at a time, by a tabulation, not difficult to one familiar with such methods, and two diagrams one can determine all the maxima stresses. The way to be pursued will be found in Du Bois' "Graphical Statics," Appendix, § 7, p. 350.

39. To find that portion of the shear at any section which is resisted by the web or braces, we can draw a line in the stress diagram parallel to a tangent to the rib at the desired point, and deduct the amount of the load line intercepted between it and the extremity of H from the total shear, or resultant of vertical forces, as already explained in §§ 19 and 20, and the remainder will be the desired vertical component of the stress in the web. It is not practicable to draw a shear diagram unless the form of the rib is previously defined; therefore, after we have discussed the parabolic and circular ribs, the reader can doubtless work up any special design of this class for himself. The tabulation and the diagrams will be similar to the ones then produced, but easier to be constructed. We have not cared to demonstrate at this time the truth of certain statements in the preceding sections, which conveniently came in this connection, because we expect they will become evident as the work progresses, and they are not essential to the line of argument.

One advantage possessed by this type of arch is that changes of temperature have no straining effect, for the crown rises and falls without affecting the two halves of the arch injuriously. If the crown sinks a little, the value of H will be seen, from Fig. 5, to be very slightly increased, while the curve of equilibrium will practically go with the arch.

40. We propose to apply the facts which have been developed thus far to the arch whose centre line is a parabola. This curve is chosen as one form because it is, as proved in § 34, in perfect equilibrium under a load distributed uniformly horizontally over the entire span. As in the case of a suspension bridge, so in some arches of iron, the major part of the steady load consists of a platform and such other parts as are distributed in accordance with this requirement, (the arch itself and the vertical posts which carry the platform giving a somewhat greater intensity per horizontal foot as we approach the springings), so that for the former portion as well as for the travelling load over the whole span, the arch will be subjected to no bending moments, and there will be no stress on the bracing. Then again, the parabola for a given rise and span is easily plotted and designed; and lastly, the determination of the curves of equilibrium, for the cases taken up, will be simpler than for circular arcs, and will naturally prepare the way, by rendering the reader familiar with the steps of the analysis. It may be well to add here that a circular segmental arch whose rise is not more than one-tenth of its span is so nearly coincident with a parabolic arch of the same span and rise, that the investigations which follow will apply with sufficient accuracy to such flat segmental ribs.

(*To be continued.*)

THE ASHTABULA DISASTER.

VERDICT OF THE CORONER'S JURY.

After a large number of sessions, extending over a period of more than two months, the coroner's jury, convened for the inquest on the victims of the Ashtabula accident, brought in a verdict, on March 8, which is given in substance below. Much testimony has been taken, and the case has apparently been very carefully considered. The findings will be seen to differ materially in their imputations of blame from what many have come to expect as the result of an ordinary inquest. The jury have employed no uncertain phrases and the verdict is in harmony with the convictions of all competent persons who have inspected the wrecked structure or studied the expert testimony. We have heretofore reproduced in our columns the most material portions of the evidence, and a consideration of those extracts, together with the clear description of the sizes of parts and the methods of joining and fastening, which we quoted in our issue of February 17, p. 46, from the letter of Mr. E. S. Philbrick, C. E., will enable our readers to judge of the facts for themselves.

At a time when the knowledge of the theory and practice of iron bridge construction was not nearly so widespread as at present, indeed when bridges of that material were comparatively rare, although engineers could then have been found of sufficient experience and competent to advise on the proportions and details of the contemplated design, the designer of this bridge undertook to improve on the wooden Howe truss with which he was familiar by substituting iron throughout. The top chord and braces were therefore made up of an assemblage of six inch I beams, bearing an analogy to the separate strands of a wooden top chord, and to the sticks of timber used in the diagonals. Cast angle blocks were retained, modified to suit the number and arrangement of the abutting pieces, and, upon the bridge proving weak, additional braces of the same character were added, the additions requiring some other work, in the way of chipping and cutting, which could not fail to be detrimental.

There was a decided lack of any means of making the several pieces which were placed side by side act as one member, the thimbles and yokes which correspond to the packing blocks and bolts of timber construction being entirely insufficient for the purpose. The fact also that the ratio of the length to the least diameter of a compression member has a very serious influence on its power of resistance to strain seems to have been unknown or lost sight of. It is agreed that there was sufficient iron in the bridge, but that, through injudicious arrangement, and a division of a member into several parallel pieces, almost independent, instead of a disposition of its material in such a form as to adapt it to withstand a thrust, this iron, in place of being a source of strength was an element of weakness by reason of its dead weight. The bridge is estimated to have weighed from 3,000 lbs. to 3,200 lbs. per lineal foot. We might call attention to other points of faulty construction, but will leave our readers to make such calculations for themselves, from the data given in the paper referred to above, as will satisfy them of the different points of weakness in the design.

The verdict was preceded by the following statement:

"It is from a careful consideration of the evidence elicited from professionals and experts that our verdict is made up in the matter of the bridge, and should it seem severe upon the railway company, or upon any of its past or present officials, it is because the truth, as shown by the evidence, demands it at our hands. We cannot do less and feel that we have discharged our duty. Mr. Amasa Stone, president of the company at the time of the erection of this structure, had been for years a prominent and successful railroad contractor and builder of modern Howe truss bridges. With the undoubted intention of building a strong, safe and durable wrought-iron bridge upon the Howe truss plan, he designed this structure, dictated the drawing of the plans and the erection of the bridge without the approval of any competent engineer and against the protest of the man who made the drawings under Mr. Stone's direction, assuming the sole and entire responsibility himself. Iron bridges were then in their infancy, and this one was an experiment which ought never to have been tried or trusted, to span so broad and deep a chasm. This experiment has been at a feaful cost of human life and human suffering. Unquestionably Mr. Stone had great confidence in his own abilities, and believed he could build and had built a structure which would prove the crowning glory of an active life and an enduring monument to his name. The testimony of competent and skillful engineers is, that subjecting an iron bridge to a severe strain as a test before using it in carrying on the traffic of a railroad is of no value as showing its ability to bear repeated strains. It only shows that it bore the test that time, and it may have permantly crippled it so that its final failure was only a question of time. The sure rule is to have a large margin of safety as shown by a careful computation and distribution of the strains. That the officials of the railroad regarded the bridge as safe we have no doubt as two of them were on the train that went down, and all were more or less frequently passing over it."

Then follow the several findings, the portions which are of professional interest being as here given. In addition, the verdict holds the railway company responsible for failure to comply with the State law of May 4, 1869, in regard to heating apparatus so constructed that the fire in it shall be extinguished upon the car being wrecked; it also attaches blame to those persons who failed to apply water to the burning cars by means of the steam pump and fire engines. The jury states that the fall of the bridge was the result of defects and errors made in designing, constructing and erecting it. A great defect, and one which appears in many parts of the structure, was the dependence of every member for its efficient action upon the probability that all, or nearly all, the others would retain their position and do the duty for which they were designed, instead of giving to each member a positive connection with the rest, which nothing but a direct rupture could sever. The members of each truss were, instead of being fastened together, rested upon each other. Other defects were: the deficient cross-section of portions of the top chords and some of the main braces; the insufficient strength and bad arrangement of both the horizontal and vertical transverse bracing; the construction of the angle-blocks as finally modified without sufficient lugs or flanges to keep the ends of the main and counterbraces from slipping out of place; the construction of the packing and yokes used in building together the main and counterbraces at the points where they crossed each other; the shimming of the top chords to compensate for the deficient length of some of their members; the placing during the process of erection of thick beams where the plan required thin ones, and thick ones where it required thick ones.

That the railway company used and continued to use this bridge for about eleven years, during all which time a careful inspection by a competent bridge engineer could not have failed to discover all these defects. For the neglect of such careful inspection the railway company above is responsible.

That the responsibility of this fearful disaster and its consequent loss of life rests upon the railway company which, by its chief executive officer, planned and erected this bridge.

TREE PLANTING ALONG RAILROADS!

The planting of trees along the lines of the Central and Southern Pacific Railroads is a most creditable step. The *Eucalyptus* has already been set out on quite a large scale; the *Catalpa* will also be tried, and it is hoped that ties and fence posts can be obtained from them both in due time. The *Eucalyptus* is of rapid growth, and therefore well adapted for the purpose, as the wood is of excellent quality. The influence of the trees on the soil and climate is expected to be very favorable, and they may affect the rainfall in some of the waste and arid lands which border upon the railroads, and thus benefit the company. It is thought by many that forests have a marked influence upon the annual rainfall of countries; there is no doubt that they mitigate or almost prevent floods by the retention of the water, and lessen the evaporation by their shade, so that the neighboring sections may become available for agriculture. To bring about such results very extensive planting and tree protection must of course be inaugurated. The San Francisco *Bulletin* makes some interesting statements as to the steps now being taken in this direction along the above railroads, and we quote some of their remarks on the *Eucalyptus*.

After speaking of the *Eucalyptus globulus*, already planted, and almost the only species to be at present found to any extent in this country, it adds:

The *Eucalyptus marginata*, which for some time has been extensively exported from the southwest of Australia and used for railway sleepers, will be set out along the hilly tracts and ledges along the roads. The *Eucalptus rostrata*, which grows in southern Australia, and in places of which the climate and character is very similar to the redwood districts of California, will be used for river bottoms and wet lands generally. The *Eucalyptus brachypoda*, which flourishes in the arid, tropical inland regions of Australia, will do equally well, it is thought, in the desert tracks of California; and the *Eucalyptus obliqua*, which rapidly attains gigantic dimensions in the poorest of soils, and can be used for almost any purpose above ground, will be set out in those places along the railroads where the other eucalypti will not thrive. The wood of all these eucalypti, with the exception of the last named, is exceedingly tough and heavy, and owing to the resinous gums with which it is saturated, it is almost impervious to decay, and can, for this reason, be used with great advantage for sleepers and telagreph poles. Sleepers of the *Eucalyptus restrata* have been known to last over twelve years, and the wood of most of the other eucalypti is said to be a little inferior in respect to durability. It is the intention of the companies to set these trees out in triple rows on each side of the tracks, from six to twenty feet apart.

The rapid growth of all the eucalypti is one of their most marked features, and one which makes them especially adapted to such a purpose as that to which the railway companies now propose to apply them. In Algiers the average growth of a young eucalyptus is nineteen inches per month, and a two-year-old tree is frequently twenty feet in height. Supposing that the trees will grow as rapidly in this country, by the time the work of setting out the trees along the road is completed the small eucalypti that are now just starting up along the railway in Alameda county will have attained the size of ordinary trees, and only a few years will have to elapse after the completion of the work before the purposes for which the eucalypti are to be planted will be realized.

FROM the annual report for 1876, of D. Farrand Henry, Chief Engineer of the Detroit, Michigan, water works, we glean a few facts of interest. Total pipeage of the city, 187½ miles, of which 94⅗ miles is iron pipe and 92 and 5-6ths miles wooden logs. The present pumps and mains will supply about 22,000,000 gallons in twenty-four hours; but if a little time is taken for cleaning and rest as at present, not over 20,000,000 gallons a day could be furnished. If the city grows in the future as in the past, this limit will soon be reached, and unless another pump and main are shortly commenced, some cold winter's day both the old and new works will have to run to supply the demand. Families assessed 20,102; not assessed, 364; showing that nearly the whole city is supplied with water. The number of gallons of water pumped this year was 142,119,790 less than in 1875. The past winter was quite mild, and few services were frozen, while the maximum demand occurred in the month of July. The daily supply per inhabitant was 101.8 gallons, which, although 5.8 gallons less than in the previous year, is still enormous. The maximum amount pumped in one day was on the 15th of July, 13,540,800, gallons over 3,000,000 gallons less than the maximum of the previous year, which occurred during the cold spell. The mean quantity pumped for the year was 11,107,499 gallons, or 3.7 per cent. less than in 1875, but 23.2 per cent. greater than for 1874.

A table showing the number of gallons distributed in the several years from 1852 to 1876 inclusive is given, from which we extract the last ten years.

Year.	*Gallons of water pumped.*	*Average daily delivered.*	*Galls. of water for one cent cost of fuel.*
1867..	1,425,535,230	3,905,576	1,408 37
1868..	1,666,545,125	4,507,248	1,464 55
1869..	1,646,810,325	4,511,°09	1,464 10
1870..	1,866,060,068	5,112,493	1,467 74
1871..	2,300,150,605	6,301,782	1,567 42
1872..	2,782,292,578	7,601,892	1,453 64
1873..	3,193,393,948	8,762,723	1,580 76
1874..	3,289,872,635	9,013,350	1,610 18
1875..	4,207,454,260	11,527,272	1,966 73
1876..	4,065,334,470	11,107,499	2,049 79

This table also shows careful water takers that they not only have to pay for all they consume themselves, but also for what their neighbors waste. The cost of pumping each million of gallons has been $7.33; or taking the average lift at ninety feet, of raising the same 100 feet high, $8.16.

THE new manual and price list of Engineers' and Surveyors' Instruments, issued by Buff and Berger, of Boston, a copy of which we have recently received, is a well arranged and instructive pamphlet. The part upon Instruments and their Adjustments especially contains valuable matter for all who use the transit, level, etc.

In answer to a correspondent, the New Orleans *Times* makes the following statement, which, upon the authority of Mr. E. L. Corthell, is correct:

The depth of water through the jetties, upon the statement of Captain Barrett, of the Plymouth, is 24 feet. The captain made soundings from the Plymouth while passing through, and announced that as the least depth found. He did not state how close he made soundings. They were probably one hundred or more feet apart. It is well known that the scouring action of the water confined to the space between the jetties leaves the bed in a very irregular and knotty shape, therefore the Plymouth may have passed over plac s of less depth than 24 feet, and very probably did—for it is known that the main obstruction to deep water is now confined to a very limited space, viz: to the outer bar, and this seems to be very tenacious, and is scoured out very irregularly. The main delay and difficulty at this point is directly traced to the insufficient confinement and direction of the water, over one-third of which flows or is wasted over the jetties. All this water should be forced through them, and compelled to cut or scour out the bar. The Jetty Company being now flush, it will undoubtedly take steps to build up and complete the jetties.

Their success in securing deep water has been sufficiently demonstrated by the results already obtained. The absolute finality of their endeavors is only a matter of time, of course. It should be remembered that no one having the authority, or connected with the Jetty Company has ever yet asserted that there was a greater depth than 21 feet through these works. Col. Andrews, in giving his notice "to all interested parties," only stated that there was a 20 foot channel through—with a somewhat deeper channel through the shoal at the head of the passes. "Roundabout" understands that Col. Andrews now only claims a clear channel of 21 feet through the outer bar, although asserting his ability to put through a 22 feet steamer at high tide Now, can any one deny that there is a channel of 20 feet, for a government survey has established that fact.

With regard to the passage of steamers to and fro through the jetties, this is more owing to the whims and pleasure of the pilots that give them direction, than it is to the depth of water. It is quite well known that these men have been bitterly opposed to the jetties, have continually scouted their success, and are still loth to admit it. Nothing would delight them more than that they should prove a failure, as their interests are decidedly opposed to an open passage to the sea. Hence it is not unreasonable to suppose that they will use Southwest Pass as long as they can. "Roundabout" can assert positively that no vessel whatever has suffered the least obstruction or delay in passing through the jetties since they were authoritatively opened. Had this been the case, there might be some reason for doubting the results published

In regard to the ship Belle O'Brien, "Roundabout" has learned that the choice made by her captain, of the Southwest Pass, in preference to the South Pass, signified nothing more than that he knew he could get out all right that way and was ignorant of the other route. If some newspaper writer had stated without authority that the ship was en route for India, and she really went to Cork it would be about as reasonable to consider it a reflection on India, as to attribute her choice of Southwest Pass to the fact that the jetties were impassable. If she did not use the channel between the jetties, she might have done so. Her captain had a preference and he exercised the right; that was all. In regard to the steamship Mississippi, her agent informed Roundabout that the reason why she went round to Southwest Pass to get her coal was because it was to be had there. If she had taken in coal in the city she would have drawn more water than was officially announced as to be had through the jetties, not less; and, therefore, she went down without it. The coal depot being at Southwest Pass, she had to go there for it after having passed through the jetties. The statement that the Plymouth drew 19 feet when she passed up might have been an error. Possibly she only drew 17 feet, But if an error was made it was not the fault of the jetties. Her captain found at least 24 feet all through wherever he sounded. Finally, "Roundabout" will inform his correspondent that the grand object of the jetties was not to shorten the distance to Europe, but to get deep water over the bar, so that vessels of a greater draught could pass in and out unimpeded. When they were commenced—not two years ago—there was scant 8 feet over the South Pass bar. Now the world is officially informed that there is 20 feet. One would suppose that this should prove satisfactory, but still there are grumblers because there is not a still greater depth. To all such "Roundabout" would recommend patience. The same power which scoured out the first 12 feet is still at work, and may be relied upon to labor as effectively as ever.

The Milwaukee avenue viaduct, crossing from different railways at an elevation of about 40 ft., is about completed. Like many other necessary improvements, this work was contemplated for a long time before any active steps were taken to carry it out. Finally, in the spring of 1876, an appropriation of $68,165 was make for the abutments and approaches, and one of $40,000 for raising the houses on the approaches and other incidental expenses, the railroads agreeing to build the viaduct proper, except for a part between Carrol street and an alley, which the city was to erect. The work was done under the superintendence of Mr. George Wilson, Superintendent of treets and Bridges, Mr. O. C. Cheney having charge of the superstructure. The contract for the masonry of the approaches, the pile-work, and paving was awarded on the 24th of March to Mr. James Kincade, and work commenced shortly thereafter. The contract for masonry was let by the cord, for piling by the lineal foot, and for lumber by the 1000 feet. In the substructure there were used 62,700 cubic yards of filling, 7,255 yards of paving, and 2,593 cords of stone in the city's portion. The abutments of the railroad bridge took up 423 cords of stone, which is charged to the different companies. In addition to all this the city used 4,320 lineal feet of piling and 11,000 feet of pine lumber.

The contracts for the iron work of the viaduct proper were let in July, but, owing to some delay on the part of the railroads, were not signed until September last. For the southern part of the viaduct, that over the Milwaukee & St. Paul and the Danville & Vincennes Railroads, both on Milwaukee avenue and Desplaines street, the contract was let to the American Bridge Company of Chicago, for $35,320.15. Thomas Leighton, of Rochester, N. Y., received the contract for the northern half, which crosses the Chicago & Northwestern Railroad on both streets, forming a Y, and the price fixed was 34,690. This part of the work completed nearly a month ago except for the paving and sidewalks, which are now almost finished. All the plans of the iron work were drawn in the Superintendent's office, Mr. S. G. Artingstall designing the viaduct. This weighs from 500 to 600 tons, and extends 476 feet on Desplaines street, and 674 feet on Milwaukee avenue, though from this measurement must be deducted the 125 feet of the pile bridging on the former, and 176 feet on the latter thoroughfare which separates the two halves of the work. The south half is what is known as a three-span truss, and the north half a plate girder bridge. On Milwaukee avenue the approaches are about 1,200 feet in length, on Desplaines street about 800 feet. The slope is very slight,—only 1 foot in 50 on the main thoroughfare, and about 1 in 40 on Desplaines street. Besides these, it became necessary to make approaches east and west on Kinzie street, extending 320 feet in each direction.

It will thus be seen that the job was one of considerable magnitude,—in fact, the largest of the kind yet attempted in Chicago. There was some hindrance from frost but not much, and the expense is expected to fall within the appropriation, except in the cases of damage claimed by persons owning property along the line. The total expense of raising the houses, many of which are large structures, is estimated at $70,000, though this is not exact, some claims being yet unsettled. The entire cost of the work is $135,000.

The "American Society of Civil Engineers" held their regular monthly business meeting for March, in their rooms at No. 4 East Twenty-Third street, New York, on Wednesday evening of the 7th inst., beginning at 8 o'clock.

After the reading of the minutes of the meetings for February, by Mr. Leverich, the Secretary, a paper by Mr. J. F. Flagg was read on the "Formation of Levees" for the protection of the banks of rivers against the abrading action of the water, proving that such protection was sufficient to prevent the washing away of the embankments.

After the reading of the paper, a long discussion was held by the members on business pertaining to the society. Professor R. H. Thurston then gave a very interesting account of the labors of the Government Commission appointed for making tests of American metals and of which he is a member. He described how the Commission was divided into different committees, the duties of each and the amount of work which they have accomplished, showing that many interesting and valuable results have already been obtained relating to the properties of American metals, as well as how much more could be still accomplished if Congress would only consent to the further existence of the Commission. The Senate warmly supports the Commission. The opposition comes only from the House and is probably awakened by the false fears of manufacturers who think that, in the reports to be made of the grade of metals, theirs *may be* reported as being of inferior quality, thus damaging their business. In reality, though, the names of no manufacturers are to be published as furnishing either good or poor metal. The object of the Commission is to furnish a report of the strength and properties of American metal in comparison to those of foreign, showing the equal goodness if not superiority of our manufactures, besides obtaining more accurate and general knowledge of the properties of metal subject to every possible condition.

As yet but a small part of this projected work has been accomplished, and, unless the scruples of the House and the fears of manufacturers are overcome, the Commission must dissolve without fulfilling this important work.

At the conclusion of the remarks of the speaker, which were listened to with great interest by the members of the society, the meeting was adjourned.

There are three practical considerations that influence the placing of windows in any building. These are,—their use in lighting and ventilating the building, constructive convenience, and architectural effect. They are all legitimate and important considerations, in their due order, in which of course the first is the chief. He takes a foolish part who essays to determine a question of windows without regard to them all; but there are limits within which each may reaonably yield to the other. In rooms which are to be used as sitting-rooms or living-rooms, especially where there is any view to be seen, it is a crying fault to set windows so high that people in their chairs cannot look out of them with comfort. But in places set apart for special services, as churches, or where any occupation which requires concentrated attention is to be carried on, the case is quite different. In a room that is to be used only for study and writing, the important requisites are that there shall be plenty of light, and it shall come from the proper quarter, preferably from the left hand, and that it shall not be too low. These considerations secured, we should be inclined to say that between three feet and five, the latter was, on the whole, the better heights for the window-sills in a schoolroom. The light that comes in below that level is not serviceable, and there is no reason for tempting either teachers or scholars to turn their attention out of doors. The limit, however, is one within which architectural effect may reasonably be allowed to rule. One would naturally infer that this was the determining consideration in the schoolhouse referred to. But whatever may have been the real justification of the singular resolution we have quoted, the reason given for it in the preamble is as apposite as if it had been recommended that whereas the ten chimneys on the Town Hall, serving twenty-five fireplaces, rose only twelve feet above the roof, while the six chimneys on the Court House, serving only eighteen fireplaces, rose fifteen feet above its roof, therefore the six chimneys should be razeed to the height of the ten.—*American Architect and Building News.*

CORRESPONDENCE.

NEWPORT, KY., *March 12, 1877.*

Editor ENGINEERING NEWS:

SIR.—I beg leave to submit the following method of keeping level notes which I believe to be better than any that has yet been presented through your paper:

Sta.	B. S. and Height of Instrument.	F. S.	Diff.	Elevations.	Remarks.
B. M.	2.619 108.906			106.287	
24		3.2		105.7	
25		5.1		103.8	
26		4.8		104.1	
	0.364				
Peg.	101.575	7.695	—4.076	101.211	
27		8.8		92.8	
28		10.2		91.4	
+50		9.9		91.7	
	10.298				
Peg.	102.000	9.873	—9.509	91.702	
29		4.6		97.4	
30		6.3		95.7	
	5.198				
Peg.	97.961	9.237	+1.061	92.763	
+40		3.1		94.8	

Space is economized by placing back (or plus) sights and height of instrument in the same column. The height of each turning point or peg is at once checked by differences as shown. Intermediate elevations can be carried out as the sights are taken, or at convenience.

By using a plain rod with figures one-tenth of a foot in height, and the same distance apart (by figuring only alternate tenths), the leveler can read to hundredths, and thus have a check on the rodman's "call" of the sight on turning points. Besides, as it is not necessary to change the position of the target for intermediates (as it is with the slide rod) the leveler can and should verify the call by reading the rod himself when the rodman comes up, or when he moves ahead, as the case may be.

Slide rods are an abomination, from the fact that the leveler is at the mercy of his rodman, who may make any number of mistakes in reading, and there is no check on him. Another fault is, that nearly as much time is consumed on intermediate sights as on turning points. With a plain rod, however, numbered as described, the leveler can catch each intermediate as the rod is plumbed, reading to the nearest tenth (and anything closer is useless for ordinary work) and no time is lost.

[*Written for Engineering News.*]

CEMENTS AND CONCRETE.

BY BERNARD R. GREEN, C. E., PORTLAND, ME.

(*Concluded from page 61.*)

Under ordinary circumstances two men will be required at the mixer, one at the engine, one at hoisting machinery, when used, and six for preparing charges. The force of men or mechanical arrangements for bringing up materials and conveying the concrete to the work will of course vary largely with the relative location of, and communication between the different points.

The charge for this mixer should not exceed, usually a cubic yard, because, if too large, the mixing will be retarded and will require, moreover, a considerable increase of power. The size of charges and the rapidity

of succession, up to 150 cubic yards in ten hours, are limited only by the force and facilities for charging, transporting and depositing in the work, activity of the cement, etc. Eight revolutions in about one minute, for charges of about three-fourths of a yard, is a good working speed; this does not include charging and discharging. A higher speed defeats the object by generating too great centrifugal force in the contents, while too much mixing tends to give heavy stone ballast an undesirable polish, besides needlessly wearing the machinery.

The remarkable mixing action of this machine was shown by reducing the number of revolutions until it was found that even one-and-a half turns sufficed to mix ingredients, thrown in at random in due proportions for concrete, so far as to well moisten each particle. Owing to its grinding effect with coarse ballast, no auxiliary mortar mill is required. A four to six horse-power steam engine easily runs it with ordinary charges. If the reader will rotate a cubical block or box around its diagonal, he will perceive its peculiar adaptation to a stirring and mixing process.

In charging, the materials for a batch are thrown into the mixer at random the cement, sand and water having been previously rudely stirred together.

The mixed concrete should be speedily conveyed to its destination, to avoid partial setting or drying under a hot sun, and it should, if possible, arrive at such an elevation that, in dumping, it will not fall or slide more than two feet. In former years it was a common practice to throw concrete from a height of ten or twenty feet, but the expected gain of compactness by this method must have been more than balanced by the inevitable loss of uniformity in the mass caused by a separation of the coarser ballast.

When dumped in place the batch is at once spread, (preserving the mixture of coarse and fine ingredients), in a layer of such thickness that the ramming, to follow immediately, will reduce it to from 4 to 5 inches, varying with the quality of the work and the coarseness of the ballast; 6 inches being the common thickness. Four to six men rapidly and evenly ram each layer, by means of iron or iron-shod upright rammers, about 4 inches square on the face, and weighing about 25 pounds. The ramming should be performed by light, quick blows, to avoid shattering the ballast of the new, or cracking the lower layer.

At this point the practised eye detects any serious error in the proportion of water. A jelly-like consistency should ordinarily not be allowed. With Rosendale cement the amount of water should be such that a thin film is raised upon the surface of each layer only by a thorough ramming, which should then cease; but with Portland cement, carrying less water and therefore quite incoherent, more ramming is essential and it should continue until the layer is perfectly compact and unyielding.

As the work thus progresses it should be so managed that the successive layers shall be least exposed, while soft, to the drying action of the sun and air, the damaging effect of a shower of rain, or a frosty night.

A due regard for economy calls, of course, for such an harmonious arrangement of the force and appliancies, employed in the several steps of the process, that all will be in constant and steady motion.

A concrete with ballast of round particles can be more easily reduced to its smallest compass by ramming, than one composed of rough, angular or flat stones. Portland cement will bear much more sand and ballast than Rosendale. Good concrete with Portland cement may consist of cement 1, sand 4 pebbles 8, and stone 10 parts, by bulk; but a common and better mixture is, cement 1, sand 3 to 3½, pebbles 6 and stone 8 parts, making fully 1½ cubic yards of rammed concrete per barrel of cement. In England concrete is said to be commonly composed of 10 parts sandy gravel, and sometimes of 4 parts sand, and 16 of stone, to 1 part of Portland cement. A very good concrete with Rosendale cement is composed of cement 1, sand 3 and mixed stone 6 parts, making 21¾ cubic feet per barrel of cement, when rammed.

Careless measuring of materials should be carefully guarded against, and a struck measure or its equivalent invariably insisted upon for them all. The absurd practice of using the shovel, or otherwise relying on shrewd guessing in this matter, has often been the unsuspected cause of failure, more or less serious.

A block of good ordinary Portland cement concrete, containing cement, sand, pebbles and stone, in proportions of 1, 3, 6, and 8, respectively, and measuring 5½ in. × 3½ in. in section and 3 in. in height, should bear, when ten days old, a crushing weight of 2½ to 3 tons. A block of Rosendale cement concrete, measuring 8 in. × 3½ in. and 3 in. in height, and composed of the four materials in proportions of 1, 2, 4, and 4, should sustain 3 or 4 tons, at the same age. It is obvious that such small test blocks should not contain large fragments of stone.

The strength of concrete depends upon the cohesion of the matrix, its adhesion to the aggregates, the irregular bonding or interlocking of the coarser fragments, and, as before stated, upon the strength and proportion of each ingredient.

Temporary cribwork, plank facings, etc., built to confine or give external form to the work, should possess sufficient rigidity to prevent the ramming of a new layer from disturbing the edge of the previous one by the bulging of the boards, and also, if desirable, to give the work a true face. The pressure caused by ramming will badly spring a 2-inch pine plank unless securely supported at intervals not exceeding 3½ or 4 feet.

When concrete is too coarse to form against the mould a sufficiently smooth surface, the difficulty may be overcome by thinly coating the mould, or plank facing, with a mortar of the same composition as that in the concrete. If such mortar be too rich in cement it will be liable to flake off in time from the action of heat and cold.

In conducting a work in concrete, extending over many days, where the intervention of night or a period of unfavorable weather, may compel a suspension of work, the last surface, on which the next layers of concrete are to follow, should be left as nearly as possible normal to the force the work is designed to resist; as would be the case in good stone masonry; that is, normal to the soffit of an arch, inclined in a leaning or retaining wall, level in a vertical wall, etc. It is sometimes advisable to place every fresh layer of the concrete approximately in such a position. The need of the first mentioned precaution arises from the weakness of adhesion of new to old work, the joints becoming planes of least resistance. Adhesion in this case is increased by moistening the old surface and applying a thin coat of mortar to it as the new layers approach.

Artificial stones of forms and dimensions adapted to almost any position occupied by ordinary building stones, may be made of Portland cement concrete, in wooden or metallic moulds, on the work close by or in their final places, or at a distance.

The *beton agglomere* of M. Coignet, of Paris, is, without doubt, the nearest approach yet made to a perfect concrete. The main features of Coignet's system are, briefly: the use of the best limes or cements, preferably Portland cement; the least quantity of water that will serve to thinly coat each particle of sand with the matrix; large doses of sand and gravel nicely proportioned to produce the most compact mass; thorough and prolonged trituration by machinery; and finally a perfect systematic ramming in thin layers in the work.

In France and elsewhere, many very bold structures have been executed in *beton agglomere*, which demonstrated its superiority to common concrete. Years ago in the infancy of concrete making in this country, General Totten so far apprehended the true method, as developed by Coignet, as to insist that so much of it should be followed, on the government works, as was then practicable without the Portland cement and improved machinery of to day. Concrete should be a close imitation of *beton agglomere*; but this will be impossible, as to the ramming, in submarine works in contact with water, owing to the necessity of omitting this very essential operation.

Coignet's system has been fully reported upon by General Gillmore, whose book gives much valuable information on the general subject, in a condensed form.

Thus it is plain that the extensive and extending use of concrete, even beyond the usual capabilities of masonry, offers a wide scope for the exercise of ingenuity guided by scientific principles, and also that the materials and facilities available, accessibility of the work and of its often difficult parts, trustiness of workmen, and other items not to be forgotten in an estimate, operate to modify, more or less, the mode of execution and the cost of concrete work. In ordinary constructions of magnitude, say a few hundred cubic yards, the cost, in the eastern states, ranges from $5.00 to $10.00 per yard, $7.00 being perhaps more common.

Important work in concrete should never be entrusted to ignorant or doubtful hands. Imperfections may be so easily covered up that occasional inspection would be of no avail, in such cases, to prevent future failure, especially in submarine or hydraulic works. Untiring, faithful supervision is indispensable to success, while, under it, excellent work may be accomplished by the most ignorant laborers.

When a more extensive introduction of concrete shall be made in every-day building operations, a class of men skilled in the principal manipulations, may spring up and the trade of the "concrete mason" be generally recognized.

It is seen that mortars and concretes are adapted to any structure from a statuette to the grandest edifice, their general adoption being only a question of cost. Concrete house-building is not uncommon in Europe, and many examples exist in this country, while the constantly widening use of cement in drain pipes, sewers, fire proof floors and partitions, and cellars, excluding both moisture and rats, is well known. Students of the problem of street pavements suspect great value in Portland cement concrete or *beton agglomere*, in that direction, experiments having already been very successful.

A common, though too often careless and foolish use of hydraulic cement, is in the form called "grout," which consists of cement and water of the consistency of cream. Sand is sometimes stirred in when the grout is thick enough to hold it a short time in suspension. Coarse or fine ground cement answers equally well. Grout can never attain the density of good mortar and is only useful for filling joints, cavities or interstices inaccessible to mortar. A valuable application of Portland cement grout has been made by injection under a hydrostatic pressure of a few feet, into confined masses of pebbles and broken stone, where it has set firmly and made an excellent concrete. The practice is not advisable where good mortar can be properly substituted.

In concrete work, as in many things, experience and good judgment in making the most of circumstances and available materials, are essential prerequisites of success, for good concrete may often be brought out of very bad materials judiciously handled. The growing knowledge of the subject promises in future fewer instances of a lavish use of concrete to ensure safety from the results of defective manipulation.

The indifference with which this subject has been regarded in past years by the majority of engineers, even those who have made much concrete, is surprising. Whether the mysterious chemical actions involved appeared a discouraging field of study, or whether the fact that good lime accompanied by moisture would stick to a brick or stone, was considered sufficient, is not apparent, doubtless both lent their weight.

It is certainly not to be expected that every busy engineer shall acquaint himself with the details of innumerable experiments and chemical analyses, but he may acquire such knowledge as to be able to assist in enlarging the utility of concrete, as opportunities offer.

AMERICAN SCIENTIFIC AND TECHNICAL JOURNALS.

The great improvement in our American Society and periodical publications, manifested by comparison with similar papers issued ten or twenty years since, can be accepted as the best of evidence of national advance. After taking a general departure from the *elementary* physics, chemistry, mechanics, or decorative or constructive art, the paths have diverged widely in the multiplicity of ways of applied science, and are followed by parties of enthusiastic searchers for novelties or knowlekge, each party in the direction of an especial subject of interest, profit or study.

The tendency is to establish separate bodies of society organizations, which seek for members all over the land to obtain that appreciative corps of readers and those audiences which stimulate competition, and give zest to the production of the dryest of documents. The general scientific society, either national or local, must divide into sections to obtain interesting or intelligent discussion or investigation. General science, alone and of itself, without particular application, it is recognized, is merely childish—the term implies a superficiality incompatible with progress. Our American societies have, therefore, become special and national and the result has produced a series of society publications during the last ten years quite equal in importance to those which have been printed in any foreign land of the same population. We are a little apt to associate scientific publications solely with those bodies which are called professional; but the race of knowledge is now open to all avocations, and with the mechanical growth of the last century all industrial pursuits have become scientific. It is only within fifty years that chemistry was admitted to form part of a collegiate education. And none of the professions or pursuits which we now call "technical," have the sanction of antiquity as scientific. To-day, however, it is in the papers of the Society of Civil Engineers, the Institute of Mining Engineers, the Institute of Architects, the National Association of Wool Manufacturers, the Railway Master Mechanics' Association, of Master Car Builders, and numerous other associations of similar avocations, that we must look for the highest and most valuable contributions to technical science. The yearly or occasional publications of these societies are replete with novelties and matters of information.

Beside these permanent records, or American technical news journals most weekly issues, contain not only a supplementary mass of purely technical knowledge, which has been elevated by the influence of the societies to a corresponding standard of excellence, but these journals are also made to be the translators of the language of the avocation which they represent, to the comprehension and instruction of that portion of the public which has to do in business, or any other way, with the particular subject. The list of these periodicals is extended and extending. Their relative circulation and popularity, other things being equal as to merits or display, of course depend on the general usefulness of, or sympathy with, their objects. Thus a paper like the *Architect and Builder*, profusely illustrated and carefully edited, will address itself not only to the professional architects, but also to all of that numerous class who build or wish to build houses, and those who take interest in church or other public buildings. There are none, from the highest to the lowest in the community, who are not interested in buildings. Chemistry, or mining, or railway engineering may not command so many readers, even if the illustrating and editing are equally well accomplished; while other papers will only find a limited and restricted circulation and sale, with the small community of interested people, they address. Patent inventions and novelties in mechanism are objects of absorbing concern to a portion of the community, and are represented by journals of rival, and on the whole, increasing merits. The more abstruse avocations, chemistry, telegraphy, photography, etc., find expression in periodicals of the highest literary attainment, and inform and gratify respective microcosms of specialists, in unknown tongues, incomprehensible to the outer barbarian. Even the minor trades become scientific and literary, and the *Lumberman*, the *Carpet Trade*, the *Tobacco Plant* add to the stores of human knowledge, until "the ample page" can be no more unfolded, and the "spoils of time" will be lost in the waste basket, or at best, on the old book shelf.

Even the advertisements, in their descriptions and illustrations of apparatus and machinery, form no small nor unimportant part of the information, to be now and hereafter accepted as philosophical and scientific. The free use of the pencil, through the various modes of "illustration" in the current newspapers, becomes a perpetual international exhibition of the latest proposals, as well as of the established practice of mechanism in all branches of trade or manufacture. It has been a popular misconception that the scientific man was to teach the workman—the skilled artificer—the practical manufacturer. The truth is that the record has always until now been behind the accomplishment. The use and value of such record is in the perpetuation of the accomplishment as the starting point of effort by the next person who undertakes to perform the same or a similar task. But now it almost seems as if the record itself will be lost as soon as made in the multiplicity of papers and documents. It will be as finding one's route in a railway guide, to trace out any specific object from the maze of literature.

Not the least valuable or important of our scientific publications are the trades' circular books of some of the larger manufacturing establishments. One could be instanced giving the early history of the locomotive in America; another gives all the details of heating apparatus construction; while the various *tool* circulars unfold the mystery of workmanship more thoroughly than any text book of science can pretend to. All these together register the advance of year by year with ineffaceable marks—aggregately they are building up the edifice of science, and the American press of to-day is supporting with great and noteworthy ability, the growth of civilization in our country.—*Journal of the Franklin Institute for March.*

THE WEST SIDE PUMPING ENGINES.

The Chicago papers give us glimpses of an interesting and instructive dilemma in the matter of the new West Side pumping engines in that city. It is worth while to tell the story in outline from the beginning, since it illustrates a new phase in the subject of high-duty engines—a subject which has been in other aspects and with reference to special instances of practice, pretty thoroughly considered in our columns already, particularly in the acute reviews of "duty-trials" furnished by our esteemed correspondent, Mr. Theron Skeel.

In July, 1874, the Chicago Board of Public Works advertised for proposals for two pumping-engines. The gentlemen composing the Board have since retired, as we are informed, to private life, without that degree of applause from their fellow citizens which could fairly be interpreted as an "encore." But the results of their remarkable advertisement cannot be retired so easily. That document appears to have been drawn on the hypothesis that the more one required of a contractor, the more margin one would have for allowing him to fall short; or else, that in order to get superhuman results it was only necessary to make superhuman demands; or else, that Chicago being fairly entitled, was also fully able, to get by asking, the most extraordinary machine in the world; or, finally, that by setting up conditions under which the most practical manufacturers would not dare to bid, the perplexity of choice among numerous competitors would be greatly simplified; On the last supposition, the Board deserves credit for its efficient method of weeding out bidders beforehand.

The specifications called for engines, each capable of raising 15,000,000 gallons 155 feet in 24 hours, and the two ocupying not more than 50 by 30 feet on the floor of the engine house. Two boilers must be sufficient to supply all the steam required, though three were to be provided. The engines were to run continuously, day and night, seven days in the week, to be operated for one year by the contractor, and at any time during that year to be submitted to a duty-test of six consecutive days of 24 hours each, in which test they were required to perform the duty of 90,000,000 pounds of water raised one foot high with one hundred pounds of Pennsylvania anthracite, no deductions being made for ashes or clinkers. There are some other rigid requirements in the specifications, but we need not enumerate them. Engineers will readily admit that a machine capable of coming up to the tests above set forth, would probably meet all the rest.

The limitation of the boilers to two in number, for engines of 850 combined horse-power, which according to Cornish rules of high practice, would require something like 25,000 square feet of heating surface, and for which ordinary prudence in high practice dictates at least 15,000 feet, and the restriction of the engines in size, and points which look intimidating to most builders. But the "duty" requirement casts everything else into the shade. Here are engineers disputing whether a 90,000,000 duty was ever really reached in this country, on short trials, under favorable circumstances. "Where," says the skeptics, "after full preparation, with clean fires and selected fuel, has this duty been achieved?" If they are pointed to Lynn, Mass., they reply by appealing to the *Engineering and Mining Journal* of March 11, 1876, in which the Lynn engine and its performances are overhauled. If they are referred to Lowell, they quote (in the absence of full publications on the subject) the admission of the inspecting experts that the results at Lowell are in practical conformity with those at Lynn. And after Mr. Skeel's searching analysis of the tests at Lawrence, nobody will appeal to Lawrence.

But the Chicago Board of Works required that this feat, which probably no American engine, in its most inspired moments, had ever achieved, must be performed by the West Side engines *for six days running, taken without notice at any time during a year of continuous operation, and that the amount of duty should be reckoned on the ashes as well as the coal.*

"But a beaver can't climb a tree," interrupted the listener to a somewhat highly-colored narrative of animal adventure. "Can't climb a tree? I tell you he *had* to climb a tree; the dog pressed him so hard!" Was this the spirit in which the Chicago Board prepared to raise to unprecedented heights the standard of American machinery?

Whether such was their intention or not the effect was to bull-doze the constructors of steam-engines. Many persons who thought they would be held to the rigorous requirement of these specifications, and would have to remove their engines and repay all moneys received if the 90,000,000 duty was not forthcoming, sadly but honestly refrained from bidding. But parties were found to attempt the impossible, and the contract was given to a builder who had constructed other engines for the same city previously—in fact all the waterworks engines, we believe, which the city has had. No one of these engines, however, had ever accomplished more than a low average duty. The last pair, only a few months before the giving of this contract, had been examined for the Citizens' Association by a committee, which in answer to the question of the economy of the engines, reported—"The work is not accomplished with a fair degree of economy." Perhaps it is natural that one who had never come within hailing distance of a 90-million duty should underrate the difficulty of reaching it—like the man who presumed he could fiddle, but had never tried. If the builder of the engines realized what he undertook, it is hard to resist the conviction that he must have known he would fail, and that he must have relied on the numerous precedents going to show that cities would rather accept waterworks that do not fulfill their contracts, than have a great trouble and confusion and begin all over again.

The famous duty-test has been made, and the engines give between 74 and 77 million foot-pounds instead of 90 million. But they are well built, run smoothly, and fulfill the requirements of capacity; and if the old Board were in power, we do not doubt that they would be accepted. The disposition on the part of the new administration to traverse and undo the work of their disparaged predecessors may lead to a strict construction of the contract. But we do not anticipate that the West Side people will see the engines removed, as the contract requires, and their half of the city left for a couple of years longer in danger and discomfort. A Chicago paper says: "there are two things to be done: accept the engines as they are and may prove to be, or endanger the property and disturb the peace of a large number of the inhabitants of this city."

There is another possible alternative, which seems to us the best thing now practicable—namely, a compromise, for which the price of the engines under the contract is said to leave sufficient room, without injustice to the builder.

Certainly it seems severe to exact full penalties of a man who has done his best, and furnished, according to all accounts, excellent engines, merely because he has not performed what was universally deemed impossible, and certainly known to be unprecedented. But on the other hand, why should the impossible have been required, and being required, why should it have been undertaken? We are willing to believe the engineer of the Water Board desired in good faith to obtain by rigorous specifications the highest efficiency; but we must nevertheless blame him (if it was he who took this responsibility) for setting his mark so high as to exclude reasonable competition. Without assailing the motives of the Water Board, we must observe that a Board *could*, under such circumstances, make use of the excessive scientific enthusiasm of its engineer to put the work into the hands of some favored party who had the courage to promise what he could not perform. A Water Board *could*, under such circumstances, that give private assurances to the favored party that his work would be accepted somehow, though it should not reach the standard nominally set up. Thus it is evident that absurdly high requirements, however well meant, practically render the whole contract system nugatory by "bull-dozing" honest contractors, and then "counting in" imperfect returns.

Some of our best engine-builders refuse to be bound by the notion of economy involved in the results of "duty trials," and undertake only to furnish machinery at a certain price to do a certain work with reasonable economy of fuel. While this extreme may be practicable to builders of established reputation only, it is evident that in competitions where the promises, not the reputation of bidders are to be the grounds of preference, the requirements should be reasonable, in order that the construction of the terms of contract may be strict and relentless. To make the requirements of cast-iron and the subsequent interpretation of india-rubber, is to convert the system of open competition into a bull-dozing business, which is certainly a farce, and might easily become a fraud.—*Engineering and Mining Journal.*

DEAN BROS., of Indianapolis, Ind., will furnish the pumps for the city of Peoria, Ill.

SPECIFICATIONS.

FOR CONTINUING THE WORK ON THE IMPROVEMENT OF THE SAGINAW RIVER, MICHIGAN.

The work contemplated is the construction of 1 000 feet, more or less, of pile revetment, according to the designs furnished by the United States Engineer officer in charge. Also such dredging in connection with the driving of the piles, and in deepening the channels as may be required by the Engineer officer in charge.

Piles.—To be in kind as shown in the bill of materials herewith, straight, sound, and of live timber; in size one (1) foot in diameter midway between the ends; in length sufficient to comply with the requirements for driving as hereafter stated; to be squarely butted and with a point in the axis of the pile made by four flat faces, each not less than four (4) feet in length, the opposite faces converging to within four (4) inches, beyond which a blunt point with four (4) equal faces, is made on the tip of the pile, the pil s to be pee'ed for a distance not less than twelve (12) feet from the butt.

Timber.—To be straight, free from windrot, shakes, wane and other imperfections, and furnished in kinds and dimensions as shown in the bill of materials.

Slabs or Edgings used for filling to be furnished in pieces not less than twelve (12) feet long, except for filling the superstructure where the lengths of the pieces will correspond to the distance between the sets of ties.

Stone.—The minimum size of which is taken at nine (9) inches cube, or an equivalent thereto, to be in specific gravity and hardness, suitable for ballast.

Iron.—Bolts and washers to be of best quality of American wrought iron, and to conform in dimensions to the bill of materials.

No material will be accepted until it is actually in the work.

All materials to be subject to a rigid inspection by an agent appointed on the part of the United States, and such as do not conform to the specifications under which they are offered, to be rejected.

Driving Piles.—Two parallel rows of piling will be driven, the front or channel row at a distance of twenty (20) inches apart, the back row to be at a distance of thirteen (13) feet from front row, measuring from center to center, to be driven seven (7) feet three (3) inches apart from center to center, and in a direction to be determined by the Engineer officer or agent in charge. Each pile to be banded for driving and driven until its point is at least ten (10) feet below the bed of the channel opposite, and at least twenty (20) feet below the surface of the water (mean low water), and in addition each pile to be driven until it will not move one (1) inch from a force equal to eight (8) consecutive blows of a hammer weighing two thousand (2,000) pounds, and falling twenty (20) feet.

Framing Piles.—All piles to be cut off in a horizontal plane ten (10) feet above mean low water, and each pile in the outer row scored down on the outer face, so as to give a bearing against which the waling may rest, the inner face of each pile in the outer row to be slightly scored, to give a fair bearing to the binder. In all cases at least nine (9) inches of the pile between the waling and binder must remain.

Framing, Waling and Binder.—The waling and binder of pine to be put on, so as to break joints with each other, and to be held in place by a screw-bolt through every third pile. The upper surface of the waling to be two (2) feet below the top of piles. Pieces to be joined with a twenty (20) inch lap joint.

Framing Superstructure.—The superstructure, fourteen (14) feet in width, is to consist of two courses of pine timber, the first of which is laid upon the tops of the piles. Ties at intervals of eight (8) feet from center to center in length of pier, to be framed and placed as shown in tracings. All gains are to be cut six (6) inches deep, twelve (12) inches wide on the outside, and eight (8) inches wide on the inside of pier to receive dovetailed ties. Such gains to be cut on the upper side of the first, and lower side of the second course. Timbers in the consecutive courses not to break joints between the same sets of ties, and the end of no timber to approach a tie nearer than two (2) feet. The first course of timber on the back row to be joined together with a twelve (12) inch lap joint, the joint to come on the top of a pile.

Bolting.—The system of bolting to be as shown in tracings. Holes for drift bolts to be bored with an auger not to exceed seven-eights (⅞) of an inch in diameter for the entire length of the bolt to be driven. Holes for screw-bolts to be bored with an auger not to exceed one and a quarter (1¼) inches in diameter.

Filling.—Slabs and edgings used for filling to be carefully placed, the lengths in the direction of the pier, and a top-dressing of stone two (2) feet deep used to secure and settle the filling.

Dredging.—Such dredging shall be required in connection with the driving of the piles, and in deepening the channel, as may be considered necessary by the Engineer in charge of the work. The material shall be properly dumped on the bank of the river immediately below the improvement.

Approximate amount of materials to be furnished and labor performed under the present appropriation.

Pine timber framed and put in place, 80,000 feet b. m. Oak or Norway pine piles, and driving, 14,143 lineal feet. Drift-bolts, screw-bolts and washers in place,. 13,020 pounds. Slabs in place, 2,067 cords. Stone in place, 190 cords. Dredging, 3,000 cubic yds.

G. WEITZEL, *Major of Engineers.*

BUSINESS PROSPECTS OF 1877.

Many engineers have been earnestly scrutinizing the signs of the times, to see if the future offered any brighter prospects. The cessation of railroad construction in 1873 threw numbers out of employment, and the depressed state of business soon brought to a close most of the works of construction; engineering as a profession has of late been a poor means of gaining a livelihood, although probably no worse than many other occupations. When trade is brisk people are enterprising, and capitalists are on the lookout for investments; undertakings are set on foot, public and private improvements inaugurated, which call for the services of the engineer to plan and direct. Until a feeling of security and confidence spreads among the holders of capital we need not expect that any great activity in engineering circles will begin. If, therefore, we find that business is looking up, mills starting anew, repairs and renovation under way, we may fairly congratulate ourselves upon a "good time coming" soon.

There were several indications of a general revival of business last fall, but the Presidential contest in November, and the following uncertainty as to what would be the upshot of the matter, renewed the timidity which had prevailed before, and every one was inclined to wait for further developments. We now, however, gather from many sources, that everything is "on the mend," slowly to be sure, but all the more safely and strongly for that, and we feel confident that the country has fairly entered upon the beginning of better times.

It is possible that no one of the indications would alone be trustworthy, but the accumulation of evidence is too strong to be gainsaid. We propose to cite some of these facts so that every one can judge for himself. If we turn back to the railroad construction of 1876 we shall find that 2,442 miles of tracks were laid in that year against 1,561 in 1875, an increase of 57 per cent. As less track by nearly five hundred miles was laid in 1875 than in 1874, it is judged that an improvement has surely set in in this case. The manufactories in many places are starting again after a suspension of business, or are increasing their hours to full time, and, in some instances, to extra time. For example, taking the items at hap-hazard from our exchanges :—Wilson, Walker & Co. of Pittsburgh, are running full, having a very large order from the Pennsylvania and other roads to equip cars in their railroad specialties; the car-shops at Wilmington, Del., are receiving numerous orders for work, and are taking on a large number of mechanics; 3000 cars are to be called for by Southwestern railroads this spring; the Vulcan Iron Mills of St. Louis, are running full; the St. Louis Bolt and Iron Co. have large orders on their books; the St. Louis Car Wheel Works are running at their full capacity; the New Albany Rolling Mill has all it can do; The Dayton, O., Car Works have a number of orders; the business of Pittsburgh has felt a decided revival, and extra time is called for in nearly every mill. "The city of Fall River Mass., the largest cotton manufacturing centre in the country, has every one of its mills running on full time, The aggregate weekly production is 134,000 pieces of print cloths, and about 12,000 pieces of wide goods, and the weekly pay exceeds $100,000. There is no accumulation of goods, nor is there likely to be any over-production for a long time, as more than one-half of all the production of the print cloth mills is sold up to April at prices which insure a handsome profit. The balance sheet of nearly every mill in the city shows a satisfactory profit for the past six months, and some of the more fortunate show a very flattering result, while the wages of the operatives are ten per cent. higher than they were at this time last year."

In the Lehigh Valley iron works are again starting up. The low price of coal has a very favorable influence on the iron industry. The Bethlehem Iron and Steel Company has been doing an excellent business since New Year's, and its future prospects are exceedingly bright; the Crane Company are turning out a large amount of work; the Phœnix Iron Co., at Phœnixville, Pa., have secured the contract for a number of wrought iron bridges for Canadian parties, and will require the full complement of hands; the other establishments in the Schuylkill Valley are reported to be very prosperous. Works at Beaver Falls, Pa., at McKeesport, at Cleveland, O., have a good supply of orders and are running full. The Ellis Locomotive Works, of Schenectady N. Y., closed since October, have been opened with work for 400 men; the Winchester Arms Co., at New Haven, are very busy on Turkish contracts; in short, hardware, iron, and agricultural implement makers generally are doing an excellent business.

As activity in any direction helps general business also, it is well to note the great recent increase in our foreign trade. Evidence is already coming in that the Exhibition at Philadelphia has been of material benefit to us in introducing our manufactures and implements to the notice of foreigners. Inquiries are being made for our goods, sample and larger lots are being ordered, and some of our articles are displacing those of Great Britain in markets which have previously been hers without dispute, and even are competing in parts of England itself. The amount of exports is steadily increasing. The N. Y. *Bulletin* says:

"Not only are the old channels toward South America and the West Indies taking goodly supplies, but England, Germany, Russia, Italy, Australia and New Zealand are showing a gradual appreciation of the superiority of American hardware. Axes, edge-tools, axe, pick, hammer and hatchet handles, spokes, mallets, smoothing irons iron planes, meat and vegetable choppers, sausage stuffers, house-furnishing goods, fluting machines, builders' and plumbers' hardware and clothes wringers are all included in the exports, and each new order shows an increase."

Great quantities of American cottons have been sent abroad, and the shipments are increasing. Our large manufacturers are receiving letters soliciting consignments from places in which American goods have never been sold before. Representatives of several manufacturing houses say they are receiving large orders from foreign countries, principally South America, Australia, and the East Indies. Some of them have sent agents to open up trade and say that reports are very satisfactory. The goods now in demand in foreign countries are cotton and woolen fabrics, agricultural implements, weighing scales and sewing machines.

That our exports are more than our imports, as has not long been the case, is a very satisfactory state of things for us. In 1876 the excess of exports of merchandise over imports was $164,000,000. In the previous year it was only $8,000,000. The flow of specie therefore turns this way, and we find gold coming down. As the *North American* puts it—"There has been a deeper meaning than lay on the surface in the frequent items that have appeared in the English papers noting the successful appearance in British markets of one competing American product after another. Massachusetts cottons have been selling in Manchester, Connecticut edge-tools in Sheffield, and New York jewelry in Birmingham. The exports of the United States have been increasing, those of England decreasing." The Birmingham advices of the London *Times*, Dec. 25, say, "Further advices this week from Australia and New Zealand testify to the increasing growth of American competition there, and a material part of the orders sent to this country are for American made hardware, including not only edge-tools, but carriage fittings and iron work, locks, bolts, tin-plate ware, etc."

Business in America cannot fail to brighten under such impulses, and there will necessarily follow the plans for extensions, changes and internal improvements of all kinds, in which engineers are interested. We have no doubt that a feeling of confidence in a better season has become general, and such a cheerful temper is a sure precursor of better times. Let any of our readers reflect carefully on the facts we have laid before them and see whether they had not better bring out their instruments from retirement, dust off their note-books, sharpen up their pencils, and prepare for whatever may turn up. The NEWS will keep up with the times, and will promptly chronicle the inception of new undertakings.

NEW YORK CITY WATER SUPPLY.

Chief Engineer Campbell, of New York City in a report for the fourth quarter of 1876, relating to the Croton Water Supply states that the present aqueduct has a capacity of daily supply of about 95,000,000, which together with that stored in the city reservoirs is amply sufficient for the demands of the present population, and with proper guard against waste, will serve for some years to come. Assistant Engineer Benj. S. Church reports the conduit in excellent condition, in consequence of the repairs which were made during the season of drought last year, and the Chief Engineer considers that as the conduit has stood for 35 years uninjured that there is no immediate cause for apprehension. He however considers that the limit to the capacity of the present aqueduct to meet the consumption of the city is nearly, if not quite reached, unless the demand can be diminished by putting a stop to waste, which can be effected by the enforcement of the present laws, and thus postpone for some years the necessity for a new conduit, which in the present financial condition of the city is certainly advisable.

In reference to the 'water famine' which has been discussed quite freely in the past year, Mr. Campbell remarks as follows:—

The Croton River and watershed will furnish a supply of water for a city of more than double the present population of New York, and considered in connection with the additional supply which may be procured from other sources and led to the Croton basin presents the cheapest and most feasible system for the permanent supply of water to this city.

The Croton River itself being insufficient at times of minimum or diminished flow to meet the demand, it becomes necessary to resort to storage reservoirs, which can be drawn upon during the dry season. At the close of the present season (1877) there will be available two large artificial reservoirs, whose combined capacity will be nearly seven thousand millions of gallons. Adding the quantity which may be drawn from natural lakes nearly nine thousand million gallons may be relied on, in addition to the natural flow of the river, to keep up permanent and steady flow through the aqueduct. This amount may even be exceeded, as during the season occasional rains would in part refill the diminished reservoirs. Had the great reservoir now in process of construction been available during the past season the scarcity arising from the extraordinary drought of 1876—a drought unexampled for a period of fifty years—would not have been felt.

I am therefore justified in saying that when this reservoir is brought into use no scarcity can arise until the demands of the city shall exceed the capacity of the aqueduct. To make assurance doubly sure, however, and to guard against a possible breach in one of the reservoirs, it will be well to commence, within the next two or three years, a third reservoir, and to this end plans and estimates are being prepared by the Chief Engineer, so that the best site may be selected after careful comparisons and the work prepared for contract at the proper time.

The unprecedented drought of the past year and its effect upon the water supply of this city called forth many suggestions and propositions for meeting the deficiency by drawing from distant streams. I have already explained that the Croton River and basin are adequate for the supply of a city of more than 2,000,000 of inhabitants; but in investigating this important subject I have been led to look beyond the Croton basin and to consider what additional supplies may most feasibly and economically be secured for the unfailing and abundant supply of water to this great metropolis. My knowledge of the topography of the country immediately north of the Croton valley, obtained from reconnoisance, and surveys made several years ago, induced the belief that the water of the Housatonic River might be tapped and led by conduit to the headwaters of the Croton. A cursory survey recently made establishes the perfect feasibility of this plan at a comparatively modern cost. The Housatonic is a large river, having its source in the Berkshire Hills; and, in its southerly course through the State of Connecticut, approaches, at a point ten miles of the head of the Croton within two miles north of the New York State line. At this point, known as Bull's Falls, a tributary of the Housatonic breaks through the mountain range which divides New York from Connecticut, and opens a way for the introduction of a canal, by which the waters of the Housatonic may be led and discharged into the Croton basin. By means of this great auxiliary supply from a large river of the purest quality, the water supply of this great city may be considered assured, even for the distant future.

Of course legislative sanction of the State of Connecticut will be required in perfecting this plan. I will here enter into no further details of the project, as they will be embodied in a special report at some future time, but I have deemed it proper to make this brief allusion to the matter in view of its importance and of the general discussion which took place during the past season on the permanent supply of water for this city.

Plans are in course of preparation with a view to extending the high service system, by which all, or nearly all, the elevated portions of the city may be supplied by the method which has already given so much satisfaction. The power at present in use is applied up to its minimum capacity, and perhaps in the desire to afford all possible accommodation, this system has been a little too much extended. The additional works will be commenced during the present year, and will prove a valuable addition to the general water system of the city. As there are vacant lots belonging to the corporation reserved by the department for this purpose, and eligibly situated for their location, the expense will be limited to the cost of the works themselves.

The daily consumption of water by the city of Boston is twenty million gallons.

THE Secretary of the Civil Engineers' Club of the Northwest requests us to say that arrangements are not yet fully made for the excursion to New Orleans in April, but that at the next club meeting he hopes to be able to give all the necessary information concerning the trip.

THE present number completes the publication of the text of Baldwin Latham's celebrated Treatise on Sewerage and House Drainage; the remaining plates, together with the index and title page will be issued as soon as they can be got ready, when each of the present subscribers to ENGINEERING NEWS will be in possession of a volume independent of the journal itself, which, four months ago, could not be bought in America, and of which the last copies were sold at fifteen dollars each. In thus reproducing in a cheap form this valuable work we believe we will eventually draw a greatly increased attention to the subject of Sanitary Engineering, and afford the means of obtaining easily the latest information on the subject, besides directly promoting the business interests of the Engineering and Architectural professions, and with these also the interests of contractors, and of the various manufacturers whose products enter into the construction of sewers. We feel, therefore, that we are entitled to the hearty support of all these classes.

We expected to arouse considerable discussion among American Engineers on the subject of sewerage and drainage, but have not succeeded, and our original project cannot be carried out at present in its entirety. We will supplement the present treatise with a copy of specifications of sewers, and with some other matter of practical use to the professions interested, by which time the season will be far advanced and works of construction begun, when we expect to give all our available space to the matter of news gathering, and, as far as possible, assisting our readers to a weekly review of the Engineering business of the country.

IN our *Volume Two* is the valuable report of the Sewerage System of Chicago by the City Engineer, E. S. Chesbrough, together with specifications for the construction of sewers; we have a few of the numbers of *Volume Two* containing Mr. Chesbrough's Report on the Sewerage of New Haven, which can be had for twenty-five cents; the Report of the Sewerage of Boston we published in full in Volume Three, but it is out of print; another most valuable report is that of the city of Providence, R. I., by J. Herbert Shedd, Chief Engineer of the Providence water works; there is also a great deal on the subject being published by various State Boards of Health, and, we believe, some treatises on American practice are being prepared for publication. The indications are that with an improvement in the financial condition of our cities and towns, the people will be awakened to the necessity and the benefits of improved sanitary conditions in their streets and dwellings.

LAST YEAR we decided not to keep "back numbers" of ENGINEERING NEWS, and that policy will be continued even more rigidly this year, and after the close of each sucessive quarter it may be taken for granted that the chances for replacing a lost or mutilated number will be very poor indeed. Subscribers will therefore see the necessity of preserving every number, and of notifying us promptly of the loss or injury of any particular one. If anything is lacking in our method of protecting papers from injury in the mails, or in addressing them to subscribers, we want to be informed of it; but having done the best we can, we cannot be expected to stand all the expense of replacing lost or injured copies; where *we* are not to blame therefore, we expect the retail price of the papers required to be sent in all cases; it is a small sum for each individual, but may be considerable in the aggregate to us. The sheets of "Sanitary Engineering" will not be for sale after this month except in book form when the price will be very nearly, if not quite, as much as the yearly subscription to the paper which at present includes the other.

CORRECTION.

In the paper on "Cements and Concrete," current in the NEWS, on page 62, first column, seventh paragraph, second line "the quantity required" should read, "the quantity *of water* required," etc.

IMPORTANT DECISION BY THE U. S. SUPREME COURT.

The long contested suit for the ownership of the dredging machinery, formerly belonging to the bankrupt estate of Fox and Howard, was decided by the Supreme court last Monday, the 19th inst., and forever set at rest, and the ownership established in C. S. Crane, who is now president of the Chicago Dredging & Dock Co., which said corporation have been in possession of this machinery since May, 1876. The machinery in question comprises four dredges, five pile-drivers, two steam derricks, three tugs and about twenty scows.

A brief history of the case is as follows: C. S. Crane purchased the said property of the provisional assignee of the said bankrupts for $40,000, the sale being confirmed by the district court, and a day being set for the payment and delivery of the property. The assignee was prevailed upon by Conro and Carkin to receive a higher bid in the interim, for $40,500, and to have the sale to Crane set aside and confirmed to them, which was done by the district court, and the property was turned over by the assignee to them.

Crane obtained an order from the circuit court to have the case opened in the district court, and testimony taken, which was done, and the district court decided against Crane and in favor of Conro and Carkin. On a petition to the circuit court for a review, the circuit judge reversed the decision of the district judge and established Mr. Crane in his rights to the property from July 9th, 1875, with the earnings from that date, giving at the same time his opinion that no appeal could lie from his decision to the Supreme court.

Notwithstanding this, Conro and Carkin procured from Judge Davis, of the Supreme bench, an appeal upon the question of jurisdiction, which said appeal was summarily dismissed by the Supreme court on Monday last.

THE BROTHERHOOD OF LOCOMOTIVE ENGINEERS.

(*From the Nation.*)

That the recent strike of locomotive engineers of the Boston and Maine Railroad has ended in the complete and utter discomfiture of the most powerful trades-union in America is matter of public congratulation. It was the fifth movement of the kind, all emanating from the same source and carried on by the same system of tactics, which had taken place within six months. With possibly one exception all of the four preceding strikes had been successful, and the two most recent and noticeable of them, that on the New Jersey Central last autumn, and that on the Grand Trunk in December, had been brilliantly successful. They were, too, all of them part of a system, and a system which actually threatened to take the control of the train movement of the railroads out of the hands of the corporations owning them, to put it in the hands of the officers of the Brotherhood of Locomotive Engineers.

The "striking" policy, if such it may be called, of this association dates from about three years back. Up to that time its objects had been of a social and benevolent character, and in these respects it appears to have done some very good work. It was an organization into which any respectable locomotive engineer could get admitted; it inculcated principles of sobriety and self-respect, and through it a certain provision was made in cases of destitution arising from the sickness or death of its members. In 1873 it included in its numerous divisions about six thousand engineers; it was looked upon with favor by the railroad corporations, and it seemed to be the effort of those controlling it to encourage a feeling of common interest and good-will between employer and employed. The whole machinery of the organization was, however, one which admitted of a very easy perversion to other ends. It needed only to fall into the hands of demagogues; and this was almost sure ultimately to happen. It did happen early in 1874.

Up to the time of the panic of 1873 the locomotive engineers of this country, like almost every one else connected with railroads, had little cause to complain. It was with them harvest time all the year round. Competent engineers could not be found to supply the demands of new roads and the rapidly-increasing number of trains on old ones; situations were plenty; wages were high and rising. Indeed, the pay of first-class engineers kept going up until it amounted to over $1,200 a year. Then came the general railroad collapse, and with it measures of economy and reductions of pay. These, as was natural enough, when it came to their turn, the engineers resisted, and in resisting them they no less naturally bethought themselves of the Brotherhood. If they could but unite in a trades-union which should practically include all the competent locomotive engineers of the country, they might well hope to be absolute masters of the situation and to dictate their own terms. Few people who have had no practical experience in operating a railroad can realize on what good grounds this hope rested. Nine persons out of ten who talk of railroad strikes, have a vague sort of general idea that almost any one who understands a locomotive could run one on any given railroad. As well might any one who has a smattering of seamanship undertake to pilot a vessel into any and every harbor. A railroad is a very complicated concern. It is almost made up of curves, grades, crossings, switchings, and sidings; it is operated on a most complicated schedule, and it is buoyed and beaconed from end to end with targets, signals, and whistling-posts, not one of which can be safely disregarded. A competent engineer must be familiar with every in and out of his track; and while running at forty miles an hour with his hand on the throttle-lever, must know exactly where to look for each signal and how to read it at a glance. To one not accustomed to the work, the rapid approach to a great city on a locomotive in the night is almost appalling. You seem to plunge forward into a darkness made visible by the glare of the head-light; while, amid the myriad lamps of streets and houses, you try in vain to distinguish the lanterns which tell the engineer that switch and drawbridge are right, that the crossing is clear, that the station is open. All these he picks out as if by intuition, and all these a novice, no matter how much he may know of a locomotive, must learn before he can take his place. When, therefore, the engineers of a great railroad—a railroad the running of which can on no account be stopped for even a day—strike work in a body, it is with the corporation which operates it much as it is with a man who drops from paralysis. All this the locomotive engineers of the country know well enough, if those who travel behind them do not; and they knew it just as well in 1873 as they do now.

It was not long after the panic of that eventful year that the inevitable collision came. It was brought about in consequence of a reduction of wages on the leased lines of the Pennsylvania Railroad west of Pittsburgh—those worked by the Pennsylvania Company. The engineers refused to accept it, struck, and appealed to the Brotherhood for its support. A man named Wilson was then at the head of the organization, who had the good sense to see that it could not live in hostility to the railroad companies, and would soon make itself a public nuisance by a reckless use of its dangerous power. The Brotherhood accordingly refused to countenance the strike, and after a time it broke down. Chief-Engineer Wilson, however, was unable to sustain himself; the war party was in the ascendant, and, at the next election of officers, he was thrown out and P. M. Arthur was installed in his place, representing the new aggressive "striking" policy The Brotherhood now numbers some 13,000 members, and possesses an accumulated fund of about $500,000 It is controlled by three salaried officers who have their headquarters at Cleveland, Ohio, and whose power, for the time being, is practically absolute. They cannot, it is true, nominally order strikes; but nevertheless Mr. Arthur's recent assertion in Faneuil Hall, that he had only to raise his hand to stop every railroad running out of Boston, was no vain boast. During a day or two he undoubtedly could have done it. Outwardly the Brotherhood never organizes strikes; it even professes to disapprove of them. All it does is to consent to them; but its consent carries with it the support of the whole order, with all its funds and influence over individuals, while without its consent a strike is practically impossible. If made, the order will crush it out at once by supplying men to fill the strikers' vacant places. The system is, therefore, ingeniously contrived to give power and to evade responsibility for its use. Nominally, the Brotherhood is still a social and charitable institution, exerting its influence in favor of a better understanding between the railroad corporations and their employees; practically, as now managed, it is a powerful machinery for demoralizing railroad employees, organizing strikes, and rendering them effective at the cost of the public.

The Boston and Maine strike was peculiar in only one respect: for the first time the rights of the community were in that case asserted and brought emphatically to the front. The State Board of Railroad Commissioners intervened, and took the ground that, as respects its railroads, the public has rights paramount to those of either corporation or employees, and those rights have got to be respected. It is certainly very curious that this position had never been taken by any public officers before. The presence of this new and formidable opponent, assuming the burden of the contest in the name of the public, evidently took both parties to it completely by surprise. These strikes had, indeed, become of late so common that the people of the country, with characteristic good nature, seemed actually to have begun to conclude that they had no rights in the matter; that a band of discontented railroad employees had a sort of common-law right to abandon trains, block railroads, and paralyze the whole movement of trade and travel in order to settle some trifling dispute over wages, or hours of labor, or systems of promotion. That this should have been so is a singular illustration of the prescriptive privilege which labor by a sort of tacit popular consent here enjoys over capital. The engineers did, as a matter of course and without thought of being challenged in the doing, what no railroad corporation has ever dared even to hint at. It is almost amusing to think of the public indignation which would have been excited had the greatest "railroad king" the country ever saw—Scott or Vanderbilt—dared to stand up and say what Chief-Engineer Arthur said (without any idea, by the way, of the significance of what he was saying) the other day in Boston. What board of directors ever dared to suggest the idea of meeting the Granger movement by a strike? What railroad ever stopped running because it had a quarrel on its hands, and to stop was the shortest way out of it? Yet in six months the Brotherhood, to settle some trifling matters of dispute, had actually stopped four railroads; its head official was now threat-

ening "to make the grass grow" over a fifth, and publicly boasted of his power to bring to a standstill every railroad running in and out of one of our largest cities, if so doing was necessary to secure that result. And yet the public seemed to think there was some distinction to be made between such a threat coming from Mr P. M. Arthur, Chief-Engineer of a Brotherhood of thirteen thousand engineers, and Cornelius Jay Scott, we will say, the representative of ten times as many millions of dollars. Accordingly, Mr. Arthur was allowed to do on an average once a month what, if attempted, would have sent in less than twenty-four hours its railroad out of the hands of the strongest corporation in the country into those of a a receiver. It certainly, therefore, was high time that Mr. Arthur and his Brotherhood received a plain intimation from some quarter that the community had an interest in his proceedings. They have received this at last; but we have some reason to suppose that the struggle is not yet over. At any rate, the matter has assumed such magnitude, that the best way of guarding against these strikes is a question of much importance, and is now exciting great attention among railroad men.

CORRESPONDENCE.

ST. LOUIS, *March 20, 1877.*

EDITOR ENGINEERING NEWS:

SIR.—In looking over your interesting number for March 3d, I find that the "Method of Keeping Notes of Railroad Curves" on page 56 is identical in principle with that described in volume for last year in article V of "Engineering Field Work" Aug. 26, 1876, to which I refer your contributor. C. A. S.

SHAWANO, WIS., *March 15, 1877.*

EDITOR ENGINEERING NEWS:

SIR.—A lumber "famine" is now a fixed fact throughout these Northern regions. The outlook is very gloomy indeed; millions of feet of logs have been cut and skidded, but we have had very little or no snow to *bank* them, and it looks now as though we will not have any more this season, and if we do the sun is so high that it will soon melt away. The lumbermen are very despondent, and the poor choppers and sawyers more so. A general failure of the winter wheat crop here last year, followed by the present failure of the lumber "crop" will make hard times the coming season. J. M.

We think there must have been enough snow since our correspondent's letter to authorize the hope of brighter prospects, —ED.

SCITUATE, MASS., *March 15, 1877.*

EDITOR ENGINEERING NEWS:

SIR.—A considerable sum of money has been spent here and in other towns along the coast of Massachusetts, in trying to determine the relative ownership of the beaches. The ke p and rockweed which lands on these beaches make an excellent land dressing and in the event of a decision in favor of a few who claim a legal title to these beaches, all the sea manure landing there becomes the r exclusive property. Now it seems to me that this is a question of boundaries, and that a surveyor is the person to judge, as all lands bordering on the beaches are claimed to hold the beach itself by the owners of these lands. I should like very much to hear the opinion of the profession on this subject. W. Y.

ROCHESTER, N. Y., *March 13, 1877.*

EDITOR ENGINEERING NEWS:

SIR.—Your correspondent, John Ryall, refers to my communication and finds an error in the calculation in which I acknowledge him to be correct. But that does not affect the result of my conclusions in regard to the correctness of the formula as modified by Mr. Kirkwood.

I would like to obtain Mr. Ryall's views, or any other engineer's views as to the correctness of the modified formula $m = 3808 \sqrt{\frac{D^6 H}{L}}$ or $D = \left\{ \frac{m^2}{1450\, S} \right\}^{\frac{1}{6}}$

where m = the cubic feet per second, D = diameter, H = head, L = length and S = head divided by the length all in feet.

Mr. Ryall says "using the sixth root, however, the result in cubic feet is 25 and the average 50 nearly." I would like to know which formula he considers correct, the one which gives 17 or the one which gives 25 cubic feet per second. L. L. NICHOLS.

GRAPHICAL ANALYSIS OF ROOF TRUSSES BY PROF. CHAS. E. GREENE.

EDITOR ENGINEERING NEWS:

SIR.—I have just received a copy of the above named work, and I do not hesitate to pronounce it the best book on the subject that has yet appeared. It is so eminently simple as to be exactly fitted for working architects and builders, the majority of whom are neither able or willing to thresh the few grains of wheat out of the intolerable mass of chaff which so loads down many of the recent volumes on engineering matters. If a writer on technical subjects wishes to prevent the use of a book among workingmen he has only to hoist his flag with the sign of integration upon it and no one will ever trouble his work. Too many of our engineering writers at the present day seem to think that a book to be of service to the profession must be crowded with the higher mathematics, forgetting the maxim of a distinguished English engineer, that the value of mathematics to the practitioner is in inverse ratio to its difficulty. If all engineering was done by accomplished scholars there might be no harm in invoking the aid of the calculus in setting slope stakes, or in finding the center of gravity of a wheelbarrow in order to estimate the cost of earthwork; but since the bulk of real work is done by men who have forgotten their higher mechanics, if indeed they ever knew anything about it, it seems quite proper that some at least of the books should be suited to this class. Where *one* roof is put up by an architect who is familiar with the computation of strains, *a dozen* are erected by ordinary builders who simply follow the rules of their apprenticeship, not knowing whether they are right or wrong. I recollect a short time since asking a carpenter how he reckoned the strains in a wooden roof of a somewhat complex design, to which he replied:—"Strains! bless your soul, there ain't any! All I did was to make the roof strong enough to hold the load." I did not refer him to Rankine, nor bother him with *bending* or *shearing moments*, but sketched for him on the floor with a piece of chalk a diagram from Prof. Greene's book, and you should have seen that man's face light up. The roofs which *that* carpenter now builds *have* strains, and he knows where and how much they are. I have used Prof. Greene's papers on roofs, as given in the NEWS, with my students during the past year, and hereafter his book will be their manual on this subject. GEORGE L. VOSE.

Professor of Civil Engineering, Bowdoin College, Maine.

COMPARATIVE COST OF COAL AND OIL GAS.

HICKSVILLE, O., *March 21, 1877.*

EDITOR ENGINEERING NEWS:

SIR.—The cost of gas light, although one among the most serious questions of business and domestic economy, is perhaps less understood than any other matter of equal importance among the economies or luxuries of life.

Without going into an examination of the per entages of possible light obtained in actual practice further than to say that ill-proportioned burners will readily, and frequently do, cause a loss of fifty or more per cent. of light, and that it is economy to use a *small number of large burners*, rather than a large number of small ones, whenever practicable, I desire to call attention only to the cost of gas itself, and the necessary incidental expenses attending its manufacture, as shown in the following estimates of the cost of gas made from coal and from oil. These estimates show the actual cost of gas making, exclusive of interest, for the various named small productions, ranging from 1,000 to 10,000 ft. per day, and are based on coal of best quality at $6.00 per ton or oil at ten cts. per gallon, with productions in each case representing the ordinary yields obtained from these materials with first-class apparatus.

COAL GAS. 14 Candles Standard.		OIL GAS. 14 Candles Standard.	
Example No. 1.		*Example No. 1.*	
Works costing about $2,000.		Works costing about $2,000.	
Making 1,000 feet per day;		Making 1,000 feet per day;	
Wages 1 man, daily	$1.50	Wages 1 man, ¼ time	$ .40
200 lbs. coal	60	3 gallons oil	.30
Lime, repairs, etc.	70	Fuel, repairs, etc.	.30
Cost of single 1,000	$2.80	Cost of single 1,000	$1.00
Example No. 2.		*Example No. 2.*	
Works costing about $3,500.		Works same as as above costing about $2,000.	
Making 2,500 feet per day;		Making 2,500 feet per day;	
Wages 1 man, daily	$1.50	Wages 1 man, ½ time	$ .80
500 lbs. coal	1.50	7 gallons oil	.70
Lime, repairs, etc.	1.00	Fuel, repairs, etc.	.55
	$4.00		$2.05
Cost per 1,000, $1.60.		Cost per 1,000, 82 cts.	
Example No. 3.		*Example No. 3.*	
Works costing about $5,000.		Works (same as before) $2,000.	
5,000 feet per day; wages one man (higher grade)	$2.00	5,000 feet per day; wages one man	$1.50
1,000 lbs. coal	3.00	14 gallons oil	1.40
Lime, repairs, etc.	1.50	Fuel, repairs, etc.	1.00
	$6.50		$3.90
Cost per 1,000, $1.30.		Cost per 1,000, 78 cts.	
Example No. 4.		*Example No. 4.*	
Works costing about $8,000.		Works costing about $4,000.	
10,000 feet per day; wages one man	$2.00	5,000 feet per day; wages one man	$1.50
2,000 lbs. coal	6.00	28 gallons oil	2.80
Repairs, Lime, etc.	2.00	Fuel, repairs, etc.	1.70
	$10.00		$6.00
Cost per 1,000, $1.00,		Cost per 1,000, 60 cts.	

In the foregoing examples it will be observed that the oil gas works have, for the very small consumption, a decided advantage over those for coal gas in the fact that they can be readily managed so as to make a supply of gas sufficient to last for two or more days, and then can be allowed to remain with fire out, and without any care whatever, until the supply is exhausted, whereas the manufacture of coal gas should be carried on daily, with fires kept over night. One result of this is to compel, in small coal gas works, the use of *all* coke made, as fuel, and another result is that the constant attention and large proportion of fuel required make the manufacture of coal gas, on a small scale, comparatively expensive, while the oil gas-making can be carried on in a small way to almost as good advantage as on a larger one.

The grade of labor required, and amount of experience needed to manage a small coal gas works, renders it liable to higher rates of wages than for oil gas making—a liability that amounts to a certainty, bearing in mind the extra work involved in making—5,000 to 10,000 feet per day, with one man.

It will be observed, too, that as the production increases the relative difference in cost decreases, until the 10,000 feet per day is reached; but beyond that amount additional labor would have to be employed in the coal gas making and not in the oil gas, until a much larger amount is reached, so that the difference in cost per 1,000 would be greater for amounts above 10,000 feet per day, than for that amount.

While the figures here given are those of actual results in every day working, under widely diverse localities and circumstances, they are not intended to represent the cost of gas as made *and sold* by gas companies, who in the smaller cases frequently have unavoidable expenses of interest, collection, and waste, aggregating more than the mere cost of gas making materials and labor; and in some of the larger cases, whose enormous business enables them to make extraordinary terms of freights, and purchase, on coal and oil, and to economize labor of manufacture and collection to a degree unattainable by the smaller works, and to sell large amounts of residual products, especially coke, the costs of manufacture *and sale* are materially less than those here given for manufacture alone.

J. DESHA PATTON.

BOOK NOTICE.

A TEXT-BOOK OF MINERALOGY. With an extended treatise on Crystallography and Physical Mineralogy. By Edward Salisbury Dana. On the plan and with the co-operation of Professor James D. Dana. New York: John Wiley & Sons. 1877.

Professor J. D. Dana's works on Mineralogy have been for so long a time recognized as the standard in this country that any new volume, in the preparation of which he has taken an active part, is sure to meet with a hearty welcome. The need of a revision of his Manual of Mineralogy, which has not appeared in a new edition for twenty years, or of some new work, to occupy an intermediate position between the Manual and his system of Mineralogy, has long been felt by all students and teachers of the science. After the publication of the fifth edition of the System of Mineralogy 1868, Professor Dana undertook the preparation of a text-book, which should supply that need. But the state of his health was such as to prevent his carrying out the proposed plan, and the editorship of the volume was at last placed in the hands of his son, Mr. Edward S. Dana, in whose name it has just been published. The new volume is, strictly speaking, neither an enlargement, an abridgement, nor a new edition of either of Professor Dana's above mentioned works, yet in some respects it may be regarded as combining the advantages of all three, as will be seen from the following review of its contents:

Part I. (168 pp.) is devoted to Physical Mineralogy. It comprises Crystallography, both descriptive and mathematical, treated according to the system and method of Naumann, and a description of the physical characters of minerals. A generous amount of space is given to an explanation of the principles involved and the apparatus employed in the study of the optical characters of crystallized substances. This branch of the subject has acquired increased importance since the application of the microscope in determining the mineral constituents of rocks has become common.

In Part II. (24 pp.) the subject of ch mical Mineralogy is taken up. The treatment is brief, but from it any person tolerably familiar with the nomenclature and methods of inorganic chemistry can get a clear idea of the significance of the formulæ used to represent the chemical composition of mineral species. Throughout the book the new chemistry is followed in the writing of formulæ. We notice the omission of a subscript 3 after Si in the formula near the bottom of page 176.

Part III. (205 pp.) is Descriptive Mineralogy. The classification is the same as that in the last edition of Dana's System of Mineralogy. Only the most important species, however, are described in full, and the descriptions are made short by the omission of the synonymy and of nearly all the analyses. Descriptions of new species are inserted in their proper places Following Part III. there are four appendixes, comprising a synopsis of Miller's system of crystallography, rules for the drawing of figures of crystals, tables to assist in the determination of minerals, and a catalogue of American localities of minerals.

The book is handsomely printed and doubtless will meet with a ready sale.

SPECIFICATIONS *

OF LABOR AND MATERIALS FOR THE IRON ROOF-FRAME OF THE STEAM ENGINEERING STOREHOUSE, NO. 4, AT THE U. S. NAVY YARD, LEAGUE ISLAND, PA. GEN. F. A. STRATTON, ENGINEER IN CHARGE.

The Roof Frame will be built in five parts, to wit: a mansard roof frame for the central building about sixty-nine feet, three inches (69′ 3″) square, and for each of the two end pavilions, each about sixty-four feet, three inches (64 3″) square, and a double pitch roof-frame for each of the two intermediate curtains, each about fifty-nine feet, six inches (59′ 6″) wide, and one hundred feet (100′) long, as shown by the drawings.

The Materials for the roof-frame will include all the wrought iron and cast iron work shown by the drawings, or enumerated in the schedule hereto appended, or in these specifications, and all wall-plates, hold-down bolts, ties, strutts, braces, rods, plates, bolts, screws, rivets, nuts

* Owing to the amount of drawing now on hand for other matters, we are unable to re-produce that accompanying these specifications.

and washers, and all other fastenings, bearings, connections, parts and appurtenances of the roof-frame, whether shown by the drawings enumerated in the schedule, or described in these specifications, or not, so as to properly and fully execute and complete the work in a strictly first-class, and the best workmanlike manner, as required by the true intent and meaning of the drawings and specifications, or by the form, dimensions and arrangement of the buildings, as determined and directed by the civil engineer in charge of the work.

The Labor for the roof-frame will include all the mechanical and other workmanship or labor, on the materials above described, necessary and proper for constructing and erecting, adjusting, fitting and fastening the same, in place, (except setting the wall plates) in a thorough and workmanlike manner according to the drawings and these specifications, all labor for erecting and taking down scaffolds, and all other workmanship and labor, whether shown by the drawings, or described in these specifications or not, so as to properly and fully execute and complete the work in a strictly first-class and the best workmanlike manner, as required by the true intent and meaning of the drawings and specifications, or by the form, dimensions and arrangement of the building, as determined and directed by the civil engineer in charge of the work.

The Contractor will Furnish all the labor and all the materials for the roof-frame, as herein described, including the use of all the machinery, tools and appliances needed in connection therewith, and fully complete the same, ready for the wooden purlins, sheathing and other woodwork of the roof, and to the acceptance of the civil engineer in charge of the work.

The United States Government will Furnish lumber and rails for the scaffolding needed as determined by the civil engineer. The Government will also furnish the use of cars for transportation in the yard, but no locomotives, horses or carts, nor any other means or facilities for transportation of men or materials, by land or water, nor will it furnish any blocks, falls, derricks, sheers, tools or appliances whatever; but all such articles and appliances, except as herein specified, will be furnished by the contractor at his own cost, risk and expense.

Wrought Iron.—The I beams for rafters and braces, channel-bars for wall plates of mansard roofs, angle-irons, desk plates, bar irons, struts, braces, knees, ties, splice plates, bolts, screws, nuts, washers, rivets and other fastenings, and such other parts as directed, will be of wrought iron of American manufacture of the best quality for their several purposes, and free from all defects.

Cast Iron.—The wall plates for curtain roofs, hubs for center of mansard roofs, bearing boxes, purlin brackets, and such other parts as directed will be of cast iron of the best quality for their several purposes, sharp, smooth, clean, sound, and free from all defects.

Paint.—The paint will consist of pure linseed oil, the best quality of oxide of iron pigment, and a good dryer, all in proper proportions.

Form, Dimensions and Weights.—All cast iron and wrought iron materials, or parts of the frame, as herein described, will be true to the form, dimensions and weights required by the drawings, schedules or specifications, or where not so described, as directed.

Joints, Fittings and Bearings.—All joints, fittings and bearings will be close, true, and well made; and where required by the drawings or specifications, or as directed, will be planed, turned, or otherwise carefully fitted.

Fastenings and Connections.—All eyes, eye-bolts, fish plates, splice plates, knees, angle plates, anchors, screw eyes, bolts, nuts, screws, rivets and other fastenings, and connections, will be of the best form and proportions, so as to make secure, strong and perfect fastenings or connections for their respective purposes, equal to the best standard for such work, and made, fitted and fastened in the best and most workmanlike manner, as directed.

Rafters.—Each rafter will be in one piece, excepting rafters A and H, which may each be in two pieces jointed at the column supports, the joints to be dressed to a full bearing surface, and each securely fastened with two fish plates and six rivets.

Wall Plates and Deck Plates.—The wall plates F and N, and the deck plates G and O, may each be made in not more than three pieces, with butted joints, as directed.

Peak Angles, etc.—All peak angles, and other similar joints, will be secured with splice plates as wide as the flanges will permit, and as directed.

Rafters B, D, I and L.—The heels of rafters B and D, and of I and L, will be well fitted to the *Wall Plates N and F* respectively, as shown, and fastened with splice plates, as directed. Each of the wall plates F and N, will be fastened to the wall with one inch (1") bolts, two feet three inches (2' 3") long, in clear, each bolt having a large washer walled in at its head.

Rafters P and Shoes.—The heels of rafters P will be well fitted to cast iron shoes which will be bolted to Cast iron Wall Plates, Q, each of which will be secured to the wall with two one-inch (1") bolts, two feet three inches (2' 3") long in the clear, all as shown by the drawings, and as directed.

Knees.—The joints of rafters A with rafters B, and of rafters H with I, will be secured by rough iron knees of four inch by three and three-quarters inches (4"× 3¾") T iron, with legs fifteen inches (15") long, riveted to the flanges with six (6) rivets through each leg.

The joints of rafters C with rafters D, and of rafters K with L, will be secured by wrought iron knees of three and one-half inches by three and one-half inches (3½"× 3½") T iron, with legs nine inches (9") long, riveted to the flanges with four (4) rivets through each leg.

Deck Plates.—The deck plates G and O will be secured to the end of each rafter of the upper roofs by two pieces of angle iron, four by four inches (4"× 4") of sufficient length to fill the space between the flanges of the rafter and secured by three (3) rivets in each leg of the angle iron. The joints of these deck plates G and O will be made opposite the ends of the rafters and secured by an angle iron on each side of the beam and a fish plate in front eight inches (8") wide and one-fourth inch (¼") thick.

Hip Rafters A and H and rafters C and K.—The hip rafters A and four of the rafters C in the end mansard roofs, and the hip rafters H and four of the rafters K in the center mansard roof, will be secured at the apexes of the roofs to cast iron hubs, as shown by the drawings and as directed. Each rafter will have a wrought iron knee on each side of the web, one leg of the knee being riveted to the web with four (4) rivets three-fourth (¾") of an inch in diameter, the other leg being bolted to the central hub with two (2) bolts each three-fourths (¾") of an inch in diameter, all as directed. The rafters A and H will be supported on cast iron bearing boxes with turned bearings and sockets resting on *Wrought Iron Columns* of the Phœnix pattern B, three-eighths (⅜") of an inch thick. Each of these columns will be turned at the ends and closely fitted to the cast iron bearing box at its top, and to the cast iron joint box at its base. These castings at the base and top of each column will be fitted closely to the inside of the column, and bolted to it by a through bolt one inch (1") in diameter.

Braces E and M.—The braces E and M will be trussed with round rods one and three-eighths inch (1⅜") in diameter, and a strutt of the Phœnix A column pattern one-fourth (¼") of an inch thick, placed at the middle of the brace or beam.

Ties.—Two additional ties of one and three-eighths inch (1⅜") round iron will extend from the foot of each strut to near the middle of the columns, as shown and as directed. Ties of one and three-eighths inch (1⅜") will be fastened to the hip rafters A and H near the columns by means of a through screw bolt one and a half inches (1½") in diameter, and will extend thence to the center where they will be secured to a wrought iron strut which will be fitted with set nuts and fastened to the central hub, all as show by the drawings, and as directed.

Purlin Brackets.—Purlin brackets of cast iron, as shown, will be made, fitted and fastened to the rafters, as directed.

Wall Plates, etc.—The contractor for the roof-frame will furnish the castings, channel-bars and hold-down bolts for the wall plates, and give all necessary information and assistance for the proper setting of the same, the contractor for the walls of the building having contracted to set and fasten the same properly in place ready to receive the roof frame.

Painting.—All iron work will be painted with one good coat of oxide of iron paint, carefully laid on.

Scaffolding.—The contractor will erect all scaffolds, remove the same, and pile up the materials thereof near the building, as directed.

Quality of Workmanship and Materials.—All workmanship will be executed in a careful, thorough and workmanlike manner, and all materials will be of the best quality of their kind for their several purposes.

Inspection. All workmanship and materials will be subject to the inspection and approval or rejection of the civil engineer in charge of the work, who will have full power, at any time during the progress of the work, to reject any workmanship or material which, in his opinion, is not of the quality or kind required by the contract, or by the drawings and these specifications, or by the character of the work to be executed.

Rejections.—All work so rejected, will, upon notification to that effect, by the civil engineer, be forthwith taken down and rebuilt or otherwise made good to the acceptance of the civil engineer; and in case of any failure of the the contractor to forthwith take down and rebuild, or otherwise make good, as above specified, any rejected workmanship, upon being notified so to do, by the civil enginineer, then the said civil engineer may employ workmen to perform such work at the cost and expense of the contractor, and the amount of such cost and expense shall be deducted from the price to be paid under the contract.

All *materials* so rejected will be immediately removed from the premises and replaced by other materials conforming to the requirements of the drawings and these specifications.

All measurements and verifications of the work shall be made and determined by the civil engineer.

In case of dispute the decisions of the civil engineer in charge of the work will be subject to the revision and the approval, alteration or rejection of the commandant of the navy yard, or the chief of the Bureau of Yards and Docks.

Time for Delivery of Wall Plates, etc.—The wall-plates and their hold-down bolts will be delivered to the contractor having the contract to build the walls of the building, on or before the fifteenth (15th) day of April, eighteen hundred and seventy-seven (1877), or as soon thereafter as directed.

Time for Commencing and Completing the Work.—The erection of the roof-frame will be commenced not before the twenty-fifth (25th) day of April, and not later than three (3) days after the walls of the center building and its wall plates shall be ready for the rafters, as determined and decided by the civil engineer in charge of the work; and said roof-frame will be completed in place, as herein specified, not later than thirty (30) days from the date for commencement, as above specified, or at any time after said thirty (30) days, not later than ten (10) days after the entire walls and their wall plates shall be ready for the reception of the rafters, as determined by the civil engineer.

The roof-frame of the central building will be commenced and completed first in order.

As directed.—The phrase "as directed," where used herein, will be construed to mean "as directed by the civil engineer in charge of the work."

The price named in the contract will be for the roof-frame and its appurtenances complete, including all labor and materials necessary for its full and entire construction, erection and completion in place, as herein specified.

Schedule of Beams, etc.—The schedule of the principle beams, etc., for the roof-frame is as follows:—

No. of Pieces.	Section.	Weight per yd.	Marks.	Remarks.
8	12" I beam.	170 lbs.	A	Hip rafters end roof.
8	10½" I "	105 "	B	" sides " "
88	8" " "	65 "	C	Com'n rafters end roof.
88	8" " "	65 "	D	" " sides end roof
8	10" " "	105 "	E	Truss'd " supports "
8	10½" chan'l	60 "	F	Wall plates "
8	8"×¾" pl'te		G	Deck plates "
4	12½ I beam.	170 "	H	Hip rafters, centre roof.
4	10½ I "	105 "	I	" sides, " "
52	8" " "	65 "	K	Com'n r'ft'rs " "
52	8" " "	65 "	L	" " sides " "
4	10½" "	105 "	M	Truss'd " supports "
4	10½" chan'l	60 "	N	Wall plates centre roof.
4	8"×¾" pl'te		O	Deck plates " "
56	6" d'ck beam	45 "	P	Common rafters for double-pitch roof, for curtains (28 trusses).
56			Q	Cast-iron wall plates.

Cast iron wall plates Q will weigh forty-five (45) lbs. each. Cast iron shoes resting on wall plates Q will weigh forty-five (45) lbs. each. There will be twelve hundred and forty-five (1,245) purlin brackets weighing about eleven (11) pounds each, and five hundred and sixty (560) purlin brackets weighing about ten and a half (10½) lbs. each. Splice plates at heels of rafters B, D, I and L, will be made of six (6) inch by one-half (½) inch bar iron with legs having an average length of four (4) inches each. Splice plates at the peak angles of the double pitch roofs will be made of four (4) inch by five-eighth (⅝) inch bar iron, with legs each ten (10) inches long, arranged to receive the pins of the truss rods.

Fish plates for joints of the deck plates will be eight (8) by ten (10) by one-quarter (¼) inches.

Angle knees at center hubs will be made of six [6] inch by one-half [½] inch bar iron with one [1] leg two and three-quarter [2¾] inches long and the other five and a half [5½] inches long.

Angle knees at joints of rafters C and A, and of rafters C and H will be of six [6] inch by one-half [½] inch bar iron with legs each five and a half [5½] inches long.

In addition to the knees specified in the foregoing specifications for the joints of rafters A with rafters B, and of rafters H with I, and rafters C with rafters D, and of rafters K with L, there will be for each of said joints two [2] wrought iron knee plates, one on either side, to be five [5] inches wide, one-half [½] inch thick, the lower leg five [5] inches averaeg length, and the upper leg as long as the width of the flange will permit.

THE engineers for the Severn Bridge Railway report that the Hamilton's Windsor Iron Company have continued to make satisfactory progress with the contract notwithstanding the unfavorable weather prevalent during the winter. The cylinders for twelve piers are now founded in the rock and filled with concrete. The foundations of three others piers are in progress. Ten of these piers have been carried up to the full height and completed to under side of girders. Nine spans of the superstructure are erected and completed, so that about 400 yards, or one-third of the entire length, is practically finished, The swing bridge across the new canal is nearly completed. The iron work for the swing bridge over the old canal is now being delivered. The large circular masonry pier to carry this bridge (built partly in the canal and partly in the river) is well advanced and out of all difficulty of construction. The foundation for the adjoining masonry pier in the river is also nearly completed. The cast iron for cylinders machinery, etc., delivered, including those fixed, is about 2,800 tons. The wrought iron delivered is 2,400 tons. The works of the other contractors in the railway approaches are not making such progress as could be wished. The total earthwork completed is about 116,000 cubic yards. Two of the piers of the masonry viaduct at Purton (part of the Severn bridge) have been commenced. The timber viaduct across the docks at Sharpness is nearly completed. The heading for the tunnel has been driven throughout.—*Architect*, (*London.*)

Work on the Sudbury River Conduit, Boston New water works, will probably be resumed early in April.

WANTED—A TEXT-BOOK ON CIVIL ENGINEERING.

We have heard it suggested many times that there is a great need of a work on Civil Engineering which shall answer as a manual and as a text-book. We have access on the book-sellers' shelves to many volumes on special subjects, some of them possessing considerable merit, but students in a technical school, or young men working by themselves, cannot generally afford to purchase a small library and cull from a number of volumes. That we have no entirely satisfactory book is evidenced by the fact that most of the instruction on civil engineering, in our technical schools, on the theory and practice of construction, is given by lectures. Mahan's Engineering is largely descriptive; Rankine's Manual is eminently theoretical, and very comprehensive, but it is so condensed, and the author so frequently gives results and formulæ for application without the steps by which results are obtained from elementary principles, or if he gives the steps of an analysis they are so far apart, that the average student, if unassisted, can with difficulty pass from one to the other, and it is a very hard book to understand, although convenient for use when once understood. The range of the topics which he takes up is very large. Trautwine's Pocket-book has many merits and there is a great deal of valuable information within its covers. None of these, however, seem to fill the desired place.

One advantage of a book like Weisbach's Mechanics is that, owing to the detailed character of his investigations, one can take up the volume after a lapse of several years and refresh the mind upon any point without being obliged to work up a quantity of preliminary matter. Any engineer who has had occasion to look up some new problem, after a long period of work in some other line, will appreciate the advantage of this fact. The School of Roads and Bridges of France has had in course of publication for some four or five years a Manual for Engineers which, in some twenty parts, with accompanying plates, is supposed to cover about everything the young engineer ought to know. The work, if bound, makes some seven volumes of text, of about 500 pages each, and as many atlases of plates, the price, to the American purchaser, being from $120 to $150, and it costs more, therefore, than most engineers would desire to pay. The portions on building laws and such kindred matters would not, of course, be of interest to us.

What we need is a good, *sound* text-book which shall not require of the reader a preliminary knowledge of more than the general principles of statics and dynamics, with the simpler operations of calculus, and which shall give the matter that often is classed under Applied Mechanics, as also, in general, strength and resistance of materials, the theory of trusses and frames, earthwork and retaining walls, foundations, masonry, tunnels, waterworks, drainage, sewerage, etc. The author should seek the simplest demonstrations, draw from the practical experience of the field and workshop, introduce graphics, and bring out the latest discoveries and improvements.

We very much fear that we shall not get what we ask for; the work must be concise and at the same time clear, the labor and research required would be large, and the prospect of remuneration would be small. The sale of scientific books is too limited to encourage a hope for pecuniary profit from such a venture, and unless some one is moved to undertake it as a labor of love, we must be content to get our information and instruction from various authors and sources.

BURSTING OF THE STAFFORDVILLE DAM.

STAFFORD, Conn., March 27.—The dam of the Staffordville reservoir gave way this morning, causing in this village fearful damage. The following is a description of the dam and the surrounding country: The reservoir belonged to the Reservoir Company, owners of the mills on the stream below. The dam was raised six feet the past winter, and the storm last night filled it for the first time, Close by the reservoir stood the satinet mill of E. A. Converse; next the shoddy mill of Jacob Basch; then the machine shop of S. A Widen. Lower down was the Phœnix Manufacturing Co.'s cassimere mill at Hydeville, and three miles below the Glen mills cotton-warp factory stood at Glenville. The Converseville Manufacturing Company's cassimere mill and G. M. Ivess' Granite Mill for making cotton goods were on the stream at Stafford Springs, about five miles from the dam. The reservoir was about a mile and a quarter long, and averaged a quarter of a mile in width. The dam was about twenty feet high, but short, the stream bed being narrow for some distance below. The water is the head of the Willimantic river. Six years ago a dam on a tributary stream above here gave way, causing great damage. The only wire to Staffordville is owned by the New London Railroad Company.

After the correct particulars of the accident are ascertained we will publish them.

BOSTON SOCIETY OF CIVIL ENGINEERS.

The annual meeting of the Boston Society of Civil Engineers was held on the 21st inst., at Wesleyan Hall. The annual report stated that six members have been voted in during the year. Total active membership is now sixty-two. There are eighteen others delinquent for more than six months in the payment of assessments and admission fees for a total sum of $134. These persons are not now by the terms of the constitution members of the society. The treasurer reported a balance in the treasury of $703.39, while last year it was $403.39. The expenses for the year have been $251.72 Deducting some unusual expenses, the expenses for the year would have been $149.19, against $572.28 for the previous year. The following named officers were elected for the ensuing year: President—Thomas Doane; Vice President—Joseph P. Davis; Secretary—George S. Rice; Treasurer—Clemens Herschel; Librarian—E. K. Clark; Auditor—Henry Manley.

CIVIL ENGINEERS' CLUB OF THE NORTH-WEST.

The April meeting will be held on Tuesday, April 3, at the Sherman House Club Rooms, beginning at 4 P. M. Gen. W. Sooy Smith will read a paper on "New Methods of Making Iron and Steel."

The Committee on the adoption of the Metric System, will present a final report for discussion.

The Secretary will announce the particulars concerning the trip to New Orleans to attend the Ninth Convention of the American Society. The necessary expenses will not exceed $4.00 per day. Members who desire to attend can obtain, from the Secretary, certificates that will entitle them to free R. R. transportation from Chicago to New Orleans and return.

L. P. MOREHOUSE, Secretary.

BRIDGE TRUSSES.

Editor ENGINEERING NEWS:

In your issue of December 16th, last, you published an article on "Bridge Designing," to which my attention was called by an article over the initials "A. H. M.," in your paper of January 6th, 1877. In reading your article I find (as did also, "A. H. M.,") that you did not follow the Stress of *compression* put, by you, upon the diagonal in the second panel *beyond that* panel, and you seemed to be satisfied that your declaration that "the tendency to produce compression in the second diagonal, will reduce the tension by just the amount of the compression, still leaving the piece under tension," was sufficient.

Beyond the second panel you leave us in doubt as to the route taken by the stress to the other end of the truss; hence you did *not answer* the "query put." "A. H. M." did answer the query, but not correctly. This is a very interesting subject to bridge builders, and to bridge designers, especially to those who are young, or new beginners in the business; hence I hope you will allow me space to express views, long entertained by me, and which I have not seen elsewhere stated, on this subject.

I will preface what I have to write, by a quotation from the late Dr. Whewell, and also write a few propositions, which should be kept in mind when designing and proportioning bridge trusses.

"There is no force, however great can stretch a cord, however fine, into a horizontal line that will be accurately straight."

From this quotation it is inferred that, a horizontal force, however great, cannot resist a vertical force however small, *and that horizontal members of bridge trusses cannot carry, or transfer longitudinally of the trusses vertical stresses or forces.*

Proposition 1st.—A figure without inclined members, does not represent a truss.

Proposition 2nd.—A frame without inclined members, that is, with horizontal and vertical members only, cannot carry any weight as a bridge.

Proposition 3rd.—Inclined members only, in bridge trusses, can carry, or transfer longitudinally of the trusses, *weight*, or the vertical components of *weight stresses.*

Proposition 4th.—Horizontal members, in bridge trusses, transfer horizontal stresses only, and not weight nor vertical components of weight stresses; hence they are not *carrying* members.

Proposition 5th.—Vertical members, in bridge trusses, transfer weight stresses, vertically only; hence they are not *carrying* members.

Proposition 6th.—In bridge trusses, stresses cannot pass *up* compressive members, nor *down* tensile members, that is, members prepared to receive those stresses only.

Proposition 7th.—No member in bridge trusses can be made to act equally well in two capacities—compressively and tensively, that is, as well as two members would, each acting in one capacity.

Proposition 8th.—In bridge trusses the two diagonals in any panel cannot be under stress, *from weight* at the same time, and as a corollary to this proposition, two stresses *occasioned by weight*, cannot pass in opposite directions, in any panel at the same time. This is the key to the subject under consideration.

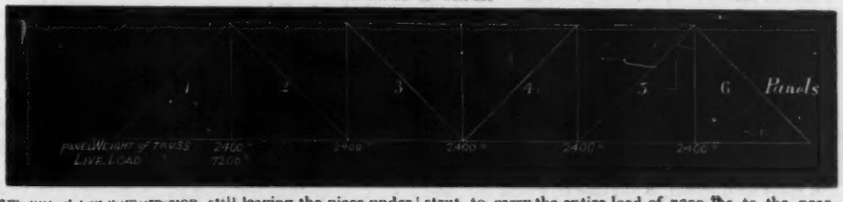
Proposition 9th.—If the *main* diagonals, in a bridge truss, are under stresses due to the weight of the bridge *only*; or if they are under stresses due to the weight of the bridge and load only, the *counter* diagonals cannot be under stress, or in action, and if the counter diagonals are brought into action to any amount of stress, or stresses, the stresses on the main diagonals will be increased beyond the stresses due to the weight of the bridge only, or beyond those due to the weight of the bridge and load only, as the case may be, to the extent of the stresses on the counter diagonals; but no more weight will be borne by the mains, than was carried by them before the counters were put under stress.

I will now endeavor to answer the "query put" in your issue of December 16th, to-wit: "If a live load of 7200 lbs. hangs by the first vertical, in what manner will one-sixth of it pass to the further abutment?"

We answer that one-sixth of *it* will not pass to the further abutment. There cannot any part of it pass through, or on, any of the members of the second panel. Two of the members are horizontal; hence cannot be carrying members—they are simply resisting members to horizontal stresses, and enable the inclined end post, or strut, to carry the entire load of 7200 lbs. to the nearest abutment, the same as would be done if the outer end of the upper chord of the second panel abutted against a vertical immovable wall, and the outer end of the lower chord of the first and second panels was attached securely to the same vertical wall, and with the diagonal in the second panel removed.

The third and last member in the second panel (the diagonal) is a tie, and besides it is under action tensively (or is supposed to be from the weight of the structure of 2,400 lbs. per panel): hence no part of the weight attached to or at the lower end of the first vertical, or

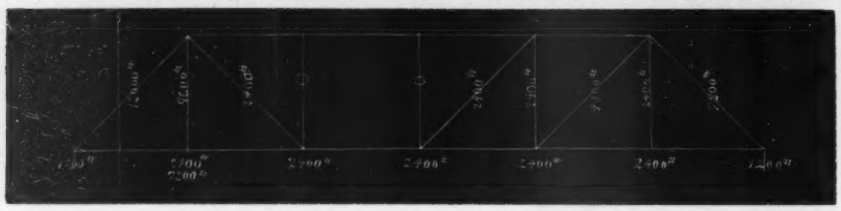
DIAGRAM OF TRUSS.



its equivalent in stress can pass *down* the diagonal in the second panel. As none of the three members of the second panel are capable of *carrying* any part of the weight through the length of the second panel, the entire weight, or its equivalent in stress, must pass *up* the vertical tie, and *down* the inclined strut to the nearest abutment—the most economical thing for it to do.

DIAGRAM OF TRUSS NOT LOADED.

DIAGRAM OF TRUSS WITH 7,200 lbs. PLACED AT THE FIRST PANEL POINT FROM THE NEARER ABUTMENT.



Now as I have disposed of the entire weight suspended by the first vertical, or the vertical stress of 7,200 lbs. occasioned by it, by carrying it to the nearest abutment, and inasmuch as a weight, or stress, equivalent to one-sixth of it must necessarily be borne, in addition to the weights of half the truss, by the farthest abutment, it is necessary that I should explain *how* that fact is brought about.

In order to simplify the question I will consider the truss, as represented, without counter diagonals, and it will hereafter be seen that they are unnecessary when only *one* panel point from the abutment is loaded with a live load, of the amount given. Considering the entire weight of 2,400 lbs. per panel (weight given) as belonging to *one* truss, it will readily be conceived that each of the diagonals, in the third and fourth panels, will have 1,200 lbs. of truss to carry, and while the truss is not loaded, the stresses due to these weights will pass up the ties and down the struts, or posts, until they arrive at the abutments. The weight of truss, carried by each of the diagonals in the second and fifth panels, is 2,400 lbs. exclusive of that due to the diagonals in the third and fourth panels, and altogether 3,600 lbs. of truss, is carried by each of the diagonals in the second and fifth panels.

Now when the live load is placed at the lower end of the first vertical, it occasions a horizontal stress in the top chord, which stress passes along the top chord until it reaches the upper end of the diagonal in the fourth panel. This horizontal stress releases the diagonals in the third panel entirely, and *compels* the diagonal in the fourth panel to *take up* and carry the entire panel load of 2,400 lbs. up the ties, and down the struts until it arrives at the further abutment.

It is the taking up and carrying of one-sixth of 7,200 lbs. *of truss*, that releases the diagonals in the second and third panels, and not compression as stated by you in your answer to the question, Dec. 16th last.

It happens, in this case, that one-sixth of the live load assumed to be placed at the first panel point, is just equal to a half panel weight of truss; hence where the diagonal in the fourth panel has taken up the 1,200 lbs. that belonged to the diagonal in the third panel (when the truss was not weighted with any live load, and hence was in equilibrium) that panel is *balanced* and needs no diagonal, in the case of a dead load, and disposed of as the live load is assumed to be.

I have now, I believe, answered the "query put" not literally perhaps, but in the sense of answering the querist.

It is not any part of the 7,200 lbs. that arrives at the further abutment, but it is an equivalent weight of truss, that is carried to that abutment.

In all cases of truss and arch bridges being unequally loaded near one end, the equilibrium of the entire weight of bridge and load is brought about, by the diagonals near the center of the bridge taking up, of the weight of the bridge, an amount equivalent to the amount of load that would be due to the further abutment, considering the position of the load relative to the abutments.

If this were not the case, the stresses due to the weight of the load would be passing in one direction, and those due to the weight of the structure itself, be in equilibrium, and be passing in the opposite direction at the same time, which I conceive to be *impossible*.

N. B. The figures on the inclined members are the *vertical components* of the stresses, and those on the verticals are the *stresses* on those members.

The panel, in the last diagram, without a diagonal, represents that no stresses are passing that panel, except horizontal stresses in the top and bottom members, and that the panel is in equilibrium. D. H. MORRISON.

DAYTON, OHIO, *March 2d, 1877.*

THE BROTHERHOOD OF LOCOMOTIVE ENGINEERS.

(*From the Nation.*)

As a practical result of their report on the strike of the Boston & Maine locomotive engineers, the Railroad Commissioners of Massachusetts contented themselves with recommending the passage of certain laws intended to guard the rights of the public in case any more strikes occurred. The community was to have the free and safe use of its railroads secured to it, no matter what quarrels might arise between employers and employed. This, of course, was as far as the Board could go, occupying the position it then did. Its members were not there to arbitrate or to suggest remedial measures looking to a removal of the root of difficulty. Their business was to act in such a way as to secure to the public the full and free enjoyments of its rights, and there, for the present at least, to stop. What was then to follow must, if it was to be of any value, result from careful investigation, and assume the shape of a thoroughly-matured plan.

One thing we do not hesitate to say, and it is a conclusion to which we believe not only all the leading railroad men of the country have come, but also every one who has given any thought to recent events—the Brotherhood of Locomotive Engineers has got to be broken up. In view of its course of late in connection with strikes, in which every right of the business and travelling public was brutally disregarded; in view of its avowed policy as defined in the recent threatening and almost incendiary speeches of its Chief Engineer, it is safe to say that its usefulness is wholly gone, and that it has become a mere common nuisance, the longer existence of which is a standing public menace. The only question is how to proceed so as to break it up most quietly and most effectually. It now numbers in its divisions nearly ninety per cent. of the experienced locomotive engineers of the country; they are bound together by a strong *esprit de corps*, and have an even inordinate faith in the really great power of their combination; the treasury of the order is well supplied, and its discipline, founded on a strong class feeling, is very effective. Altogether, it is a formidable opponent, one with which no railroad corporation would care to grapple if it could help it. Even if a strike fails, the cost of victory is something at which directors may well stand aghast. In the recent Boston and Maine strike, for instance, though the question practically at issue was whether the Brotherhood or the officials were to operate the road, it was nominally only a matter of $6.70 a day: if the officers of the road would have allowed ten cents a day increased pay to sixty-seven men, there would have been no strike. To do this, however, involved a submission to the Brotherhood, and injustice to some 1,500 other employees whose pay has also been reduced. The directors very properly, as we think, refused to yield, and the strike ensued. The corporation was completely victorious, but its victory cost it probably not less than $50,000, and possibly $100,000. On the other hand, to the Brotherhood the cost of the strike will probably not exceed $300 a day, or about two cents a day while it lasts, to each member of the order.

Under such circumstances as these the Brotherhood enters on every contest with the chances enormously in its favor. The larger and more unweildy its opponent the better. If they can but paralyze it for forty-eight hours they are sure of success. The road has got to be run; and if the corporation cannot rally from the knock-down blow and stagger to its legs at once it is lost. Accordingly Mr. Arthur has reduced the system to a science, the cardinal principle of which is instantaneous action with utter disregard of the public. A strike is secretly decided upon. Two hours, and two hours only, of notice is given, at the expiration of which every engineer stops his locomotive where it then is; stays by it two hours to give the corporation time to yield, and, if it does not, he blows out the boiler and abandons the train. Indeed, it is well if in so doing he does not take the locomotive with him. Then comes the short, sharp struggle. The road from end to end is blocked with abandoned trains, and the whole force, not only of the striking engineers but of the brotherhood, is directed to keep it so. In the case of the Grand Trunk strike, the passenger trains were stopped, amid Canada's December snow and ice, at 11 o'clock at night; locomotives were disabled, tracks obstructed, and those who undertook to work the abandoned engines were mobbed. Grand Chief-Engineer Arthur was dealing with "the enemy," and the unfortunate passengers happened to come between him and it; for what ensued he did not hold himself responsible. Like the Prince of Denmark, he doubtless thought that

> "'Tis dangerous when the baser nature comes
> Betweeen the pass and fell incensed points
> Of mighty opposites."

In the case of the Boston & Maine road the tactics were exactly the same; fortunately the circumstances were different. The corporation by a desperate effort succeeded in mustering enough men who could not be frightened, and did not care to be bought, to enable it to keep a few trains in motion during the two decisive days. To one of these men $1,500 in cash was offered, if he would leave his engine; another was assaulted and beaten; all of them were cajoled and coaxed, or jeered at, threatened and insulted from one end of the road to the other. In two days the company had caught its breath; in four days it was master of the situation. At first, however, the chances were four out of five against it; and each of those days cost it tens of thousands of dollars.

Whose turn comes next?—This is a question we have reasons to know is now exercising the minds of nearly every railroad president and superintendent—except those of the Boston & Maine and the Pennsylvania Company—in the country. These officers all know perfectly well that the majority of their engineers are members of the Brotherhood; that, as such, they cannot be relied on; and that the presence of Chief-Engineer Arthur in their ante-rooms means simply submission or fight. Of course, such a condition of affairs cannot last. It means anarchy. The only question is, how can the engineers be gotten away from the Brotherhood? Had any steps been taken to carry into effect Mr. Arthur's threat of a general strike on the Boston roads, in aid of the Brotherhood's waning fortunes on the Boston & Maine, we have understood that it would have been immediately met by the introduction into the Legislature of a law forbidding any corporation, under heavy penalties, to entrust a locomotive to a member of the Brotherhood. Such a measure, based on the principle that these men recognized an allegiance higher than the law of the State, and could not be relied upon not to abandon trains full of passengers in dangerous positions,

was, we have understood, drafted and ready for immediate submission. Practically, its passage would have broken up the Brotherhood in Massachusetts, as its members would have had to choose between leaving the order or seeking employment out of the State. Mr. Arthur, however, paused in time, and did not provoke this violent remedy. It was a measure, also, not likely to pass a State Legislature except under circumstances which are not now likely to occur, since Mr. Arthur has been taught a little discretion.

But this is a question which ought to be settled by the railroad corporations, and not by State legislatures. Indeed, it can never be properly settled on a basis of penal legislation; it must be made a matter of kindly and friendly adjustment between the employers and employed. The proper course to pursue is always a very simple one, and one which we wonder some of our rich and powerful corporations have not already adopted. They should constitute their own benevolent and life-assurance associations for the benefit of their employees. They should not leave this work to trades-unions; to do so, and thus invite outside influence, is neither sound policy nor good economy. Take, for instance, the Boston & Maine road. It had in its employ at the time of the strike 1,556 persons, of whom 67 were locomotive engineers. Had all of these been bound together in one Boston & Maine Benevolent and Life-Assurance Association, into which a percentage of monthly wages was regularly paid, no strike could have taken place. All occupations connected with running a railroad are hazardous. Both life and limb are in continual danger. Our railroad corporations are now old enough, large enough, and rich enough to take this into consideration, and systematically provide for it. The eight roads, for instance, running out of Boston, all of which only a few days since were in imminent danger of a combined strike, represent a permanent investment of $100,000,000, with the annual income of $20,000,000, and with 12,500 persons in their employ. The Boston and Albany alone employs 4,500. And these enormous corporations let trades-unions steal their men away from them! The thing seems hardly credible, and yet it is so. Plainly, therefore, it is wholly their own fault if the officers of these corporations stand in terror of Mr. Arthur and his Brotherhood. It is not legislation, but wisdom that they need. They have no business to call for penal statutes, or to look to the Government for protection. Let them protect themselves.

The Brotherhood of Locomotive Engineers is, therefore, as we look at it, now engaged in its last and most useful work. It is driving our larger corporations into creating brotherhoods of their own, turning their present mobs of employees into a regular graded service, with its promotions, its life insurance, and its pensions. The men would then be tied to the corporations by something more than the payment of monthly wages; nor would they lightly sacrifice by joining in strikes what represented the accumulation of years of service. It is no part of our business to work out the details of such a scheme. We can only say that what Mr. Arthur and his associates have done, we believe that Mr. Vanderbilt or Mr. Scott or Mr. Chapin can do a great deal better. Perhaps, however, in the whole railroad connection there is no man so well calculated or in such an excellent position to mature successfully the desired system as President Hinckley, of the Philadelphia, Wilmington & Baltimore. It wholly rests in the power of these gentlemen to destroy the Brotherhood they now dread so much. If a few more strikes are necessary to start them in the work, we sincerely hope that Grand Chief Arthur may, with as little delay as possible, supply the needed incentive.

ON THE PROBABLE ERRORS OF LEVELING; WITH RULES FOR THE TREATMENT OF ACCUMULATED ERRORS.*

BY WILFRED AIRY, B. A., M. INST. C. E.

As the members of the Institution are no doubt familiar with the processes of leveling, it is not intended to do more than glance at the various precautions taken to provide against accidental errors. In most engineering works it is unnecessary to give much attention to the small discrepancies between the results arrived at by different observers; but in the case of a complicated system of long lines of leveling, such as is required for the levels of an entire country, the aggregation of small errors becomes formidable, and the proper treatment of them requires considerable method and skill. In the present paper the author has dealt with errors of leveling under the following heads:—

A. The different classes of errors which occur in all leveling operations.

B. The probable errors of leveling on ground of different degrees of inclination, as deduced from standard leveling in different countries.

C. The treatment of probable errors in the case of a complex system of leveled lines.

D. Remarks on the instruments and methods of working used in accurate leveling.

A. The Different Classes of Errors which occur in all Leveling Operations.

These are of three kinds, viz.:—

(1) Mistakes.

(2) Instrumental errors.

(3) Errors of observation.

The first two of these are not of the nature of graduated errors. "Mistakes" arise from want of care in reading the staff, or the bubble, or in booking the readings; as well as from the foot of the staff being shifted between the readings, and from want of care in holding the staff vertical. The only effectual safeguard is to check the work throughout by independent observers, and to divide the distance into short sections defined by benchmarks. As a check on individual leveling, it has been customary in Great Britain and in India to graduate the staves differently on the two sides, and always to read both sides of the staff: the readings of the two sides ought, of course, to differ always by a constant quantity. To secure the foot of the staff from being shifted between the readings, it is usual to place the staff either upon a peg driven into the ground, or upon a three-cornered iron shoe jammed down firmly on the ground. To insure, as far as possible, the verticality of the staves, it is usual to have small levels, or plummets, let into them at one side, and in India the staves were guyed upright by ropes.

(2) Instrumental errors are either errors of collimation, of level, or of form of the telescope, the last-mentioned only coming into question when the spirit-level is not permanently attached. None of these will affect the accuracy of the leveling, so long as the instrument is always placed exactly midway between the staves: this condition is essential to all exact leveling, and has been observed in all operations of a standard character. Along with instrumental errors must be classed those of length and graduation of the staves: in general the graduation of the staves is very uniform, but errors of absolute length are not uncommon, and in all exact operations a standard bar should be kept at hand for testing the length of the staves.

(3) Errors of observation are the small graduated errors inseparable from all operations which depend upon human nerves and judgment. For any single operation they are very small; but, as they are repeated with every operation, they may amount to a considerable aggregate at the termination of a long course of work. For different persons the errors will, in all probability, have different values, as they depend upon natural and acquired keenness of estimation. They are, in fact, due to the degree of uncertainty existing in the mind of the observer as to the exact value of the several quantities which he has to estimate, and it is to be presumed that his estimate of these quantities is as likely to exceed as to fall short of the true value. Errors of judgment (but not 'mistakes') also occur in reading the staves, and the bubble; and errors also arise from small oscillations of the staves from the vertical, but not from carelessness or any determined bias on the part of the staff-holder. To these must be added slight alterations in length of the staves caused by changes of temperature or moisture: which, though sensible in amount, were found in the Swiss leveling to be very slow, small, and irregular, so that no law could be safely deduced. The combination of these produces the final error, and it is with these that the present paper is chiefly intended to deal. There is no safeguard against errors of observation, but their amount may be reduced by the selection of observers of natural quickness of sight and decision, well trained to the work.

Dr. Whewell and Colonel Walker have noticed that, in general, the results of leveling any given line differ considerably according as the line is leveled in one direction or the other. Colonel Walker attributes this mainly to the disleveling effect of the sun's heat upon the instruments, and to errors of reading the bubble caused by the oblique direction in which the light falls upon it. To obtain reliable results it is essential that every line should be leveled both ways, and the mean of the results adopted as the true value, as the various circumstances of heat, light, ground, weather, and indeed everything, would stand a chance of being reversed or modified.

B. The Probable Errors of Leveling on Ground of Different Degrees of Inclination, as deduced from Standard Leveling in different Countries.

In general the results obtained by different observers on a long line of leveling are different. But there are not unfrequently cases, even on very long lines and on steep ground, in which the results of the different observers agree closely, and it is usual to quote such close agreement as a proof of the accuracy of the common result. Nevertheless, it is always highly probable that the result arrived at is incorrect: for no observer could reckon on arriving at the same result each time, if he re-leveled the section several times over, and yet he would probably be unable to say that one result was more correct than another. Therefore the chances are greatly against the probability of the common result being correct, and it may be assumed that the result is in error, but that the errors of the different observers have all run in the same direction, and are of equal amount.

Since then it would be quite unsafe to form conclusions as to the probable error of the leveling on any line from the actual discordance of the observations on that particular line, and since it is necessary to be furnished with values of the probable errors in order to combine the results on different lines in the most probable manner, it becomes necessary to form rules or tables for arriving at the probable errors either by calculation or inspection. This subject has received much consideration from Messrs. Hirsch and Plantamour at pages 108–121 of the "Nivellement de la Suisse."

Obviously the amount of the error on any given line will, in general, depend upon the length of the line and the steepness of the ground. If length of line only were considered as affecting the error, and (e) be taken to represent the amount of the error which may be admitted as fairly due to a single mile of the leveling, then the probable error on a line of length (k) miles will be $e\sqrt{k}$ (See Airy's "Theory of Errors of Observation," art. 53). But when there is much difference in the nature of the ground, it is certain that the error for any line will greatly depend upon the sum of the ups and downs on that line. Errors in the lengths of the staves and in small oscillations of the staves will certainly be proportional to the sum of the ups and downs: also, in all probability, steep ground will lead to high elevations where the effect of the wind and rain will be more severely felt, and the uncertainty of the readings will in consequence be greater. If the sum of the ups and downs only were considered as affecting the error, and (f) be taken to represent the amount of the error which may be admitted as due to a rise or fall of 1 foot, then the probable error on any line will be (f) times the sum of the ups and downs on that line.

In the application of these formulæ to the case of a 'polygon,' Messrs. Hirsch and Plantamour have apparently made no attempt to combine their effects. They have deduced the values of (e) and (f) from the closing error of the polygon, by assuming that the closing error is uniformly distributed over the entire length of the polygon, and have applied either one or other of the formulæ to determine the corrections to the several sides of the polygon, as a first approximation. Then if, as was usually the case, some of the sides of the polygon, went to form adjacent polygons, new values were ascertained for the corrections to those common sides from similar operations with the adjacent polygons. These new values were then imported into the original polygon, and a new closing error obtained for that polygon, from which in the same way as before second approximations to the values to the several sides were established. And a similar method was pursued for third and fourth approximations.

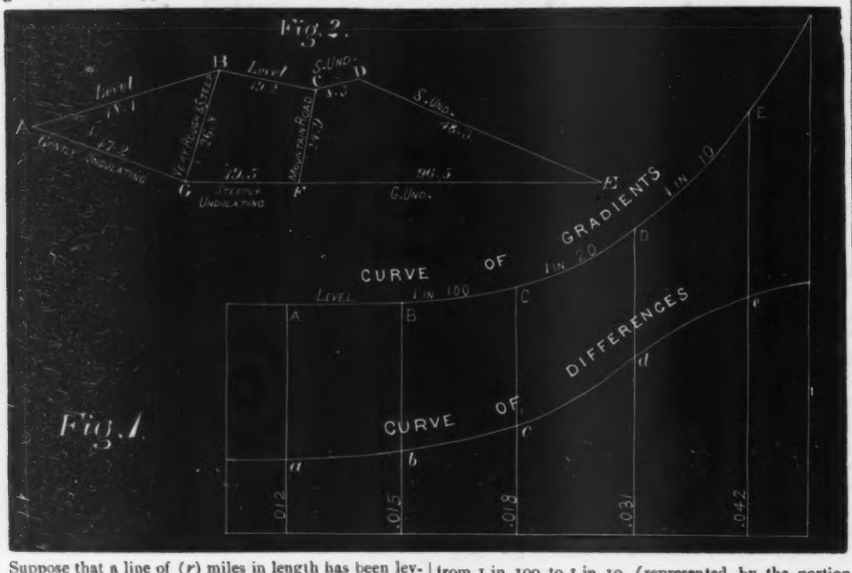
This plan appears open to several objections. First

*From the Proceedings of the Institution of Civil Engineers, London.

it is certain that the error due to any given line depends both upon the length of the line and the contour of the ground, and whatever formula is used for the corrections should have regard to both. Secondly, it is very unsafe to use the actual closing error of a polygon as the basis of the corrections which are to be applied to the several sides: for it might well happen that the closing error was exceedingly small, while the error at intermediate points was large. Thirdly, the method of successive approximations, as described, is laborious and unsatisfactory. As soon as any network of lines has been completely leveled, no matter how complicated it may be, there is no difficulty in applying the Theory of Probable Errors so as to obtain directly and simultaneously the most probable values for the levels of all the points of the system.

In considering the question of dealing, in a satisfactory way, with the adjustment of the levels on a complicated system, it occurred to the author to frame Tables of Probable Errors, such as would be applicable to the circumstances of the different lines of the system. The data for framing such tables would be drawn from the official records of standard leveling in different countries, and the value of the tables when framed would depend in a great degree upon the mass of statistics reduced in order to compile them. Through the courtesy of Colonel Clarke, R. E., of the Ordnance Survey Department, and of Colonel Walker, of the Survey Department of India, the author has obtained access to the original records of the check leveling executed on long lines in Great Britain and in India, and he has extracted similar information with reference to the Swiss leveling from the "Nivellement de la Suisse."

A critical examination of the discrepancies between observers on the same line of levels, showed that the average amount of the discrepancies depended very much upon the inclination of the ground. If the average inclination between two benchmarks was steep, no matter whether parts of the distance were uphill and other parts downhill, then the discrepancy was greater for that section than for another section on which the ground was flatter, and this rule was found to hold with great regularity. It was therefore possible to frame a Table of Errors suitable to different inclinations of ground, and the application of the table is as follows:



Suppose that a line of (r) miles in length has been leveled, and that the character of the ground corresponds with one or other of the classes mentioned in the Table. The probable error due to a single mile of leveling on such ground would be taken from the Table by simple inspection, and this probable error multiplied by $\sqrt{r}$ would give the probable error due to the whole line. By this method due account would be taken of all the principal causes of error, as depending upon the contour of the ground and the length of the line, and the probable error for each line of the system would be determined on a broad and uniform basis.

The results of the reduction of a large mass of observations in Great Britain, India, and Switzerland are given in Table I. There appeared to be no practical advantage in quoting the average differences for very small changes of inclination of the ground, and the differences are therefore given for the gradients included between broad and well-defined limits of inclination. Whenever the differences were tested for gradients not quoted, the law of increase of differences with increase of inclination was observed to hold good with considerable uniformity. Thus, for instance, in the English leveling the average differences in a single mile were—

	Foot.
For gradients below 1 in 100	0.024
Do. between 1 in 100 and 1 in 50	0.035
Do. do. 1 in 50 and 1 in 20	0.042

TABLE I.—AVERAGE DIFFERENCES in a SINGLE MILE of the RESULTS OBTAINED by TWO OBSERVERS on GROUND of DIFFERENT DEGREES of INCLINATION in GREAT BRITAIN, INDIA, and SWITZERLAND.*

	Great Britain.	India.	Switzerland.
	foot.	foot.	foot.
(1) Average difference in a single mile on ground nearly level, and in very favorable circumstances of weather	**.0230**	**.0142**	.0125
(2) Average difference in a single mile on ground of a slightly undulating character, where the gradients do not exceed 1 in 100	.0238	.0168	.0148
(3) Average difference in a single mile on ground where the gradients lie entirely between 1 in 100 and 1 in 20	.0379	**.0208**	.0183
(4) Average difference in a single mile on ground where the gradients lie entirely between 1 in 20 and one in 10	**.0566**	**.0350**	.0308
(5) Average difference in a single mile on steep and rough ground where the gradients are frequently steeper than 1 in 10	..	..	.0416

*The quantities marked in black figures are estimated from the analogy afforded by the Swiss Leveling, as no direct data could be furnished.

To exhibit more clearly the nature of the law which regulates the magnitude of errors in leveling, the author has prepared a diagram [Fig. 1], in which the successive changes of gradient from 'level' to upwards of 1 in 10 are represented by a curve of gradients, and the corresponding magnitudes of 'differences' by a curve plotted from the observed results of the Swiss Leveling. Such a diagram may be usefully applied to obtain the probable difference of results on ground of variable character. Thus, for instance, if the gradients on a given line range from 1 in 100 to 1 in 10 (represented by the portion B C D E of the upper curve) in about equal proportions, the probable difference of results might be taken pretty correctly by inspection from the corresponding portion, *b c d e*, of the lower curve. But the inspection method will not be quite accurate, and it may be convenient to form accurately a table which would be applicable to most circumstances of leveling.

[*To be continued.*]

IMPROVEMENT OF NAVIGABLE RIVERS.

The Illinois House, on the 1st inst., adopted the following resolutions relative to the improvement of navigable waters (especially rivers) in this State. The Senate, recently amended the first section of the preamble by striking out the words therein relating to injudicious expenditures of the Government funds, and adopted the resolutions:

WHEREAS, The Mississippi Valley has heretofore received from the general Government but meagre appropriations for the improvement of its rivers and harbors, and these small appropriations have been for the most part injudiciously expended; and

WHEREAS, The Mississippi Valley and its slopes produce the great bulk of the agricultural surplus of the country, and the producing class of our people have been and still are compelled to ship the products of their industries to tide-water over expensive lines of railways, at a cost of 20 per cent. of the gross value of such products, a tribute they can illy afford to pay monopolists, and from which they of right ought to be protected by the general Government; and

WHEREAS, If the navigation of the Mississippi river and its tributaries should be improved by the judicious expenditure of liberal appropriations made by Congress, our surplus products could reach tide-water by way of New Orleans at a cost of 6 per cent. of their gross value, saving to the Western producers 14 per cent. of the gross value of the products to their industries, which they would lose if compelled to reach tide-water through unnatural channels; and

WHEREAS, By means of the first liberal appropriation made by Congress for the removal of obstructions to the navigation of these Western rivers, the mouth of the Mississippi has been successfully opened to commerce, but the benefits resulting from the consummation of the great enterprise can only be partially enjoyed by the inhabitants of the slopes and valley of the Mississippi unless their means of egress be facilitated by improving the navigation of these Western rivers; and

WHEREAS, By judiciously expended appropriations commensurable with the benefits which would result therefrom, the channel of the Mississippi river between the mouth of the Missouri and the Gulf of Mexico might be shortened nearly 200 miles, by which, together with the removal of the bars which retard the velocity of the current, this great stream might be subdued, and the immense adjacent territories of productiveness, now worthless from annual inundations and resulting malaria, might be reclaimed and utilized; therefore, be it

Resolved by the House of Representatives, the Senate concurring herein, That the Congress of the United States be, and is hereby, memorialized to make just, liberal, and sufficient appropriations for the permanent improvement of the navigation of the Mississippi river and its tributaries, and their harbors; and in the expenditure of any money which may be so appropriated, and in all contracts for such river and harbor improvements, that Congress adopt like rules and stipulations as in the contract with Captain Eads, by the act of Congress approved March 3, 1875.

Resolved, That the Governor is hereby requested to transmit a copy of this memorial and these resolutions to the Governors of Wisconsin, Minnesota, Iowa, Missouri, Arkansas, Louisiana, Mississippi, Tennessee, Kentucky, Indiana and Ohio, and request the co-operation of their Legislatures in advocacy of this memorial and resolutions.

Resolved, That this memorial and resolutions be transmitted through the proper channels to the Senate and House of Representatives of the United States.

DISCUSSION ON HOUSE DRAINAGE.

At the meeting of the "New Haven Engineering Society," held at North Sheffield Hall recently, a paper on the subject of House Drainage was read by City Surveyor, Charles E. Fowler, from which the following abstract is made:

The subject of House Drainage is one that is not as familiar to the general public as its importance deserves. Under this method is treated the most approved method of laying the drains, and the proper arrangement for their ventilation. As a general thing, in our own and in other cities, the work and arrangement of house drains is faulty, both in design and execution. It is not claimed that it is intentionally so, but simply for the reason that the matter is not thoroughly understood. The common plan or arrangement of a house drain as usually carried out here, was to carry the connection from the sewer or cesspool to some convenient point under the cellar bottom, and there connected with the soil and waste pipes from the closets, bath-tubs, sinks, bowls, etc., on the floors above. Usually at each inlet to the soil or waste-pipe, there is placed some kind of a water trap, although not always done. Between the house and the sewer or cesspool there should *always* be placed a proper trap, yet the statement was ventured, that of all the dwelling houses in this city that have drain pipes leading from the interior of the house to the sewer or cesspool, not one-fourth of the number have traps so arranged. This is a very strong statement, and reflects very discreditably upon the intelligence of our citizens; still it is believed to be true. With a house so constructed the result would be a free and unobstructed channel for the foul, impure or offensive air of the sewer or cesspool, to rise in the pipes to the interior of the house, and seeking escape at every crack and opening. And escape it would, for it is al-

most impossible to make and keep the interior drain pipes air-tight. The exposure of the pipes to the difference in the temperature of the atmosphere on the outside and of fluids on the inside, causes contraction and expansion, and rendering almost certain the breaking of the cement or filling of the joints of the pipes.

The air which is found in our sewers and in cesspools is hardly such as we would desire to have in our dwellings, and very often it is absolutely dangerous to health. It is believed that there is more danger from the air found in cesspools than in sewers, for in the latter there is circulation and better opportunity for purification. But in either case, for the safety of our lives, its entrance into houses should be prohibited. The air from sewers or cesspools may escape very freely in our dwellings before its presence will be suspected, and that this happens very often there can be no sort of doubt. A large amount of water thrown into the soil or drain pipe will, in most cases, empty the small traps at the sinks and bowls of the house, unless there is some provision for admitting air at the upper end. In cases where there is a trap located between the house and the sewer or the cesspool, in addition to the traps at the inlets to the drain, there is another danger that is often overlooked, and that is from the air which may be confined in the drain and soil pipes themselves.

This air, like that of cesspools and for the same reasons, is considered more detrimental to health than that found in the sewers. Whenever a large amount of water is thrown into the pipes a certain amount of air must escape, and it is reasonable to suppose that air confined in such quarters would be impure and unwholesome. If no ventilation or escape pipe has been provided, this air will force the traps at the bowls, etc., where it meets the least resistance. If any portion of the soil or drain pipe is defective or leaky, the foul air will escape at such times, if at no other. Such is the case in many houses in this city, and it is known that many cases of sickness and perhaps death, have been caused by the neglect or carelessness of the owners, builders or designers of our dwelling houses. The remedy for these defects is deemed to be easy of solution and of practical application. The drain pipe, soil pipe, branches and all connections *must* be made air-tight, and all reasonable means taken for keeping them so. At every inlet should be located a proper trap. From a point just back of this trap a pipe must be carried up from the drain to the surface of the ground, and there connected with a leader or rain-water spout from the roof. The soil pipe inside the house must be carried up its full size to a point above the roof, as a ventilating shaft. Experience has shown that owing to the warmer atmosphere of the houses, and the consequent heating of the internal pipes, that there is a constant circulation of air through the pipes—coming down the outside pipe and passing up the soil and ventilating pipe—which cannot be otherwise than of great benefit as a purifying agent. Communication should also be established between the ventilating shaft or pipe, and all parts of the branch pipes where there is any danger to be apprehended from confined or stagnant air, bringing the air circulation as near as possible to every trap on the premises. By this arrangement, all stagnation is prevented, the pipes are constantly exposed to the purifying influence of currents of air, and the water-traps throughout the house are relieved from pressure, both of the pent-up air on the one side and the atmospheric pressure on the other.

A number of well-known authorities on the subject were quoted, and explanations of the plan were given by illustrations. Quite a lengthy discussion followed which was participated in by Professors Brewer, Trowbridge, Norton and Newton, Dr. Lindsley, Messrs. Hill, Pierce, Kelly, Ferry and others of the society. The remarks of Prof. Brewer, president of the Board of Health, were especially interesting, and he related several instances of defective workmanship and bad results that had come under his observation.

A MODEL NAIL MILL.

Among the most flourishing of the great industries of the iron regions of Pennsylvania and West Virginia which are now showing the effects of reviving trade, the celebrated Benwood Nail Works at Wheeling, W. Va. stand prominent. The old mill which was totally destroyed by fire nearly a year ago has been replaced by one of the finest Nail Mills in the world—a fire-proof building constructed solely of iron, fire-brick and stone, unsurpassed for excellence of plant and convenience for the purposes designed for by any similar factory in the country. The following we extract from the *Wheeling Sunday Leader* of March 11th:

Below the forge, which is 94 by 116 feet, sixteen puddling furnaces are in operation in a building measuring 75 by 177 feet, and 14 more will shortly be set at work in a building 100 by 62. These furnaces are all new and are constructed upon the latest and most improved models. The coal that supplies these furnaces is dug out of mines owned by the company, and which are but a few rods away. The cars are filled in the mines and run on a short incline to the elevated railway that runs around the whole mill and close to the walls. It is then dumped at the feet of the furnaces and the great desideratum of cheap coal is attained with the least modicum of expense.

At the upper end of the puddling department and separating it from the heating department are the mammoth engine of the main building and the eight boilers that supplies it and the engines in the machine shop, water works, and factory, with steam. Above are the muck rolls, shears and ore crusher. These are all combined in two departments measuring 57 by 146 feet and 156 by 75 feet. The main engine is considered a master piece of machinery and is 40 inches cylinder and 48 inches stroke. The boilers are all 28 feet long and 44 inches in diameter. To the left are the machine and blacksmith shops, and water works. The first is a splendidly appointed workshop containing the finest machinery and a small army of the best workmen to be had. The water works stand apart from any of the other buildings. Three immense tanks stand upon three solid towers about twenty feet in height. A large Cooper steam pump in a small building behind them keeps the tanks always full, while steam pipes during the winter season prevent the water from freezing. This water arrangement itself is quite an institution, which a small city might be proud to own.

But we leave this portion of the works and enter the nail factory. The only difference in construction we noticed here from other mills was in the great width of the factory. Our conductor expatiated on the latter advantage showing what an immense labor of handling is saved. A railway track surrounds the whole of the interior of the factory, and the nails are taken from under the machines, hand picked, placed in kegs, rolled on the small cars and are then stored in the factory along the walls, or else are run out to the door and shipped. From one of the doors of the factory an inclined tramway runs to the river. A branch track of the B. & O. R. R. also passes the doors, and whether the nails are to be shipped by rail or river the vessel is at the door, and hauling or extra handling entirely dispensed with.

The factory building is 120 feet wide and 300 feet in length. It contains 110 nail machines at present and a number more are soon to be added.

By the courtesy of Major. Loring, we were permitted to make minute inspection of every department of this magnificent establishment, and we were much impressed with the system upon which the whole was planned.

From the first processes through which the iron is passed until it is loaded on the boat or cars every department seems managed upon a system that is perfect in itself and harmonious to all the rest. Every device that can save time, labor or trouble, is placed just in the right spot and the aggregate work done by them must result in an immense saving to the company each year and enable it to put the very best quality of nails on the market at the closest margins.

The Benwood mill now occupies about two acres of ground. Situated upon a bold bluff of the Ohio river, about two miles below Wheeling, and with inexhaustible supplies of fuel, and unsurpassed shipping facilities we look to see it in time become one of the largest and most important manufacturing establishments in the world. It is under the management of splendid business men, whose experience in the nail business is ripe and valuable.

CORRESPONDENCE.

PAWTUCKET, R. I., *March 24, 1877.*

Editor ENGINEERING NEWS:

SIR.—I have read and tried several of the forms for keeping levels recommended in your paper, and think for accuracy and convenience of work, that recommended by Mr. Davis is far the best, especially in convenience, as in cold or damp weather, when leveling for profile work I am obliged to reckon on the field only the Bench Marks or T. P. and not even then unless transferring heights for marking, as I note in the intermediate readings as read by the Rod-man and do the reckoning in the office. Respectfully yours,

A. R. SWEET

REDUCTION OF LEVEL NOTES.

OTTAWA, *March, 17, 1877.*

Editor ENGINEERING NEWS:

SIR.—In your issue of 10th inst. is a letter from Mr. J. B. Davis on this subject, in which he refers to my former letter.

I hope neither he nor any of your readers will take my remarks as disparaging the American system. I have always used it, since I came to Canada, on account of its quickness in field work. By this system there should be no excuse for a leveler not having his levels reduced in the field. There is only one operation needed, and this can be done while the rodman is moving from station to station.

Levels can be reduced in the field by the English system, but the greater amount of calculation may interfere with the extent of the day's work. For this purpose, only back and fore sights need be made up as Mr. Davis suggests.

Mr. Davis does not meet my argument, that an error at an intermediate point, cannot be discovered at the time. For example, suppose that the elevation of station 26 had been reduced 106.13, instead of 104.13, the error could not have been discovered before the instrument was lifted, whereas by the English mode it would have been found out at the fore sight, thus

back sight	2.619
fore sight	7.695
difference	5.076
Elevation of B. M.	106.287
Elevation station 29	103.211
difference	3.076

showing at once a difference or error in reduction of 2 feet. This the leveler would discover at once, when taking the difference between his back and fore sights, before lifting his level. No experienced leveler would think of lifting his level until he had applied the check, which is a check on the reduction as well as on the fore sight reading.

I always apply the back and fore sight-check, after reducing from "height of instrument," at every move.

The reduced levels ought to be checked in the office by the English or Mr. LeBaron's mode, to check intemediates, especially in permanent levels.

I am glad to see Mr. Davis pointing out the importance of equalizing back and fore sights. Young levelers do not pay that attention to this point which it deserves. I have sometimes had much difficulty in impressing its importance upon beginners.

ALAN MACDOUGALL.

JERSEY CITY, N. J., *March 20, 1877.*

Editor ENGINEERING NEWS.

SIR.—I have used in my business for about fifteen years the method of keeping level notes given below, and as it may be of use to your readers, in view of the interest taken in the subject by some of your correspondents, I send you a copy of a page of one of my old note books.

I find that while the old method requires the use of two pages, if it is necessary to make extended remarks, by this method only one page of the note book is required.

By the use of the letters I and P the height of instr. and turning points are distinguished at a glance from the other values.

The column of stations is placed next to the column of values, for convenience in platting.

LEVI W. POST.

COLUMBUS, O., *March 22, 1877.*

Editor ENGINEERING NEWS:

SIR.—As a contribution to the discussion between Messrs. Clemens Herschel, A. B. Hill, F. H. Smith, Alf. P. Boller, Chas. Bender and others, relative to the merits and defects of the different systems employed in the construction of iron bridges, it may not be out of place to hear the opinion of a man, whose authority on this subject is unquestioned in Germany, where his famous work on the "Theory and Calculation of Iron Roof and Bridge Constructions" is used as a text book in the best polytechnic schools of the country.

In the first chapter of this work, Professor August Ritter, of the polytechnic school at Hanover, Germany, says: "In the larger constructions of roofs and bridges, the proper and most economical distribution of the materials is the principal consideration; not only because the cost of the materials in such constructions is generally large, when compared with the cost of labor, but principally for the reason, that the applied material forms a dead load, upon which not unfrequently the practicability of the entire structure depends. A perfect construction should always fulfill these requirements: 'that everywhere the full capacity of resistance of the materials is employed, and that nowhere any superfluous material is expended.' These conditions may be otherwise stated in this form: 'All parts of the structure shall be able to bear the maximum of the admissable strain under the most unfavorable condition of the load.' With ends or bars, which are either subjected to extension or compression in the direction of their length, this condition is readily satisfied, because all parts of the cross section of such bars or rods are equally strained. With bars, however, whose resistance to flexure is brought into requisition, the above condition is never satisfied, because the strains resulting from

HIGHWAY AND RAILROAD BRIDGE, 250 FEET SPANS, ST. JOSEPH, MO. BY THE DETROIT BRIDGE AND IRON COMPANY.

flexure are always distributed unequally over the section of the bar. A good structure should therefore be composed, if possible, of members in which only longitudinal strains occur; never strains of flexure; in other words, of bars and struts subject to extension and compression.

"The tendency to conform to this general rule is becoming already quite apparent in practice; as larger structures are being undertaken, they approach more nearly to the standard above required.

"The desire to save material gradually led from the solid rectangular beam to I and II shaped cross sections, and the substitution of separate bars for solid plate, has finally led to the various combinations of bars and rods, in which only longitudinal strains occur. The iron roofs, and the lattice and truss bridges of the present day are samples of these constructions.

' 'In order to fully satisfy the above named conditions, it is necessary that the connections of the bars employed in a structure should be formed by simple connecting bolts; (hinges). Whenever, instead of the simple coupling bolt, which admits of the free rotation of the bar around its connecting point, a rigid connection is attempted by riveting, as is still the practice in many lattice and truss bridges, the object is always partially defeated, for the reason, that in all such cases transverse strains are inevitably added to the longitudinal strains.'

"Aside from the disadvantageous distribution of the material, such imperfectly constructed combinations suffer also from the more serious defect, that the determination of the actual maximum strains is more or less removed from control, while in all theoretically correct structures the strains of every member can be readily ascertained with the utmost accuracy. It is a noticable fact, that those constructions which approach nearest to the theoretical perfection are always those whose strains are the most easily determined."

After quoting the above authority it would be preposterous to add any individual views of my own.

To argue from the failure of the bridge at Ashtabula in favor of riveted structures and in condemnation of other connections, will now, in the light of recent testimony, no longer be considered admissable. That unhappy structure seems to have combined all the defects of all systems but had none of the good qualities of any system.

M. I. BECKER,
Chief Eng. P., C. & St. L. Ry. Co.

HENDERSON, KY., *March 22d, 1877.*

Editor ENGINEERING NEWS:

SIR—I write this for the benenfit of those of your readers who have not tried binding, and who desire to save their periodicals for future reference. It seems rather extravagant to pay as much for the binding of one's papers as for the papers themselves. With this feeling I undertook my own binding, and succeeded, much beyond my expectations. In two evenings I bound the three volumes of ENGINEERING NEWS, and two other volumes of periodicals. I find the binding quite strong and very neat. I use one of your your "reading cases" for the current year, and find it answers a good purpose in keeping the numbers neat and smooth and quite ready for binding. The method I adopted is as follows: If creased, dampen the papers and subject them to pressure. Between two shelves fasten vertically on the front edges four strings equal distances apart. Let the end strings be somewhat nearer together than the papers are long; bind with the first and last numbers a piece of stout manilla paper to serve as lids to the volume; lay last number on the lower shelf against the strings; place your hand around the strings and between the middle leaves of the paper; stick a needle with waxed thread through one of the end strings and through the paper and draw it through on the inside—opposite the next string, from the inside; stick the needle through the paper and through the string; draw it through from the outside; stick the needle through the same string and through the paper and draw it through from the inside; proceed as described to the end. Place the next number and proceed in like manner; and so on with the balance of the numbers; then unfasten the strings and cut them to say within three-fourths of an inch of the volume; with stiff flour paste smear well the back of the volume; take a strip of muslin wide enough to cover the back and lap say one and one-fourth inches over on the lids; paste the muslin well and apply it to the back of the volume, and over on the back edges of the lids; place the book under pressure before a fire to dry the paste; when completely dried, by means of a keen knife and steel, straight edge, trim the edges, and you will have a volume quite as well bound for your purposes as though you had paid a book binder $3.00 for binding it. It is done in quite a short time, and the odd work was to me quite interesting. As the patent medicine men say "try it."

A.

CHICAGO, *March 20, 1877.*

Editor ENGINEERING NEWS:

SIR.—As you seem to be interested in the question of the economy of heat in the steam engine, I shall continue my comments on G. W. P.'s statement, after making a few remarks on his last letter. About the pressure of the gases your readers may form their own opinion from what has been said; but I entirely differ from him when he says that "the change from heat to work *is not the question* that is generally understood." Now, do I again fail to interpret his first letter where he says that "among the studies of economy of heat in the steam engine," for I understand him to mean the economical conversion of heat into work. With me the only question is the economical change of heat into work by means of the steam engine.

Before returning to G. W. P.'s queries, I will quote a little from a book about superheaters. I find in "The Compound Engine," by A. Mallet. New York, 1874, page 7: "In 1834, Ernest Wollf [a German we infer from his name] took out a patent [No. 6,600] of an engine described as compound, as nowadays constructed. A part of the description of this patent reads as follows: 'it is sometimes useful to have between the cylinders an intermediate reservoir to regulate the pressure; this may be placed with advantage at the base of the chimney so as to maintain or raise the temperature and the pressure of the steam in its passage from one cylinder to the other.'"

Having said so much without touching the question in hand, I will commence where my last left off. The illustration of expanding the steam down to 200° of temperature was used as G. W. P. had used it and as it would serve to illustrate a point. No engine should be so constructed or so proportioned to its work as to expand its steam to 200° for the following reasons: if it is a high-pressure engine the pressure of the piston on the steam side, will be less than the pressure of the atmosphere on the exhaust side; so that there will be a partial vacuum holding the piston back until the exhaust port opens, when the air will rush in until the piston returns and expels it with the exhaust steam. If it is a condensing engine the heat of the exhaust steam should not be greater than 100° or 110°, the heat of the condenser and the waste water from the condenser; this comes as a natural consequence of expanding the steam in using it economically by expansion.

In regard to putting the steam into a superheater, how is this to do any good? The steam is to leave the large cylinder at a temperature of 200°; this will be something less than the pressure of the atmosphere; if the superheater should increase the pressure, then this would increase the back pressure in the exhaust to the same amount, so what is to be done with it to make it pay for all this complication of machinery?

The same trouble ensues if the heated gases are carried around the cylinder, as this would involve the carrying of flues to the engine, then around the cylinder and then back to the chimney; besides being in the way of doing anything to the engine, it would soon become so coated with soot that it would be of no value, or it would be of no value, or it would have to be swept once each day the same as the boiler flues, and carrying the gases through a flue containiug so many bends would require so much more chimney, that taking all things into consideratio, the saving would be too small to pay.

With regard to steam jackets, I only know of four engines that have been built in Chicago having them, and of these, two have not yet been started, and I do not think that there are more than six all told. I state these things as I intend to write you a letter on this subject.

C. W.

NOTES.

Rock Island wants an Opera House.

Story county, Iowa has a new Court House costing $70,000.

Quincy wants to try the merits of Nicholson pavements.

Independence, Iowa, recently voted $10,000 for a new School House.

LaCrosse, Wis., will erect a new $8,000 School House the coming season.

The Chicago Dredging & Dock Co. was incorporated March 27, 1877, with capital of $55,000.

The American Society of Civil Engineers will meet in its ninth annual convention at New Orleans April 24.

In excavating for city purposes in Denver, gold was found in paying quantities.

Egan, the architect for the Cook Co. Court House, has compromised his claim of $26,000 by accepting $15,000.

It is generally understood that a critical examination of the Lake Crib will soon be made, so as to learn the exact condition of the portion under water.

NOTES — (*Continued.*)

Three thousand joint stock companies have failed in England in the last seven years. Their total nominal capital was $1,500,000,000.

The iron mountains of Missouri, according to Prof. Waterhouse, contains enough ore above the surface to afford an annual supply of 4,000,000 tons for 200 years.

The estimated cost of the new Water Works at Burlington, Vt., is $50,000. The total expenses of the present system are $17,894 per year, and the receipts about $19,000.

The first suspension bridge in the United States is said to have been constructed by James Finley, over Jacob's creek, on the turnpike between Uniontown and Greensburg, Pa., in 1796.

The United States government has built a concrete wall at Minneapolis, Minn., for the protection of St. Anthony's Falls. The wall, which cost $900,000, is 1,875 feet long, 40 feet high, 7 feet wide at the base, and 4 feet at the top.

The city of Peoria has discovered that her Holly Water-Works are useless, and has voted in her Common Council to discard them and put in a Dean pump. The present machinery is very inadequate. Only five-inch streams can be thrown at once. There is great dissatisfaction among the business men at the whole Water-Works system.

The Department of Public Works, Chicago, has issued to James Kincaid an estimate of $226 for work on the substructure of the Milwaukee avenue viaduct. The total value of the work so far completed by Mr. Kincaid is $63,923. It is expected the viaduct will be in condition for travel by the first of next month. All that remains to be done is the putting up of the side rails.

All the anchorages of the Suspension Bridge, Niagara Falls, have been opened, and with the exception of the first one, have been found in good condition. The repairs that have to be done are now completed, and passenger traffic will be resumed as soon as a certificate of the safety of the bridge can be obtained from three of the most able engineers of the day.

After much waiting and preliminary the Baldwin Hotel, San Francisco, Cal., is open. The inaugural ceremonies included a supper and grand illumination of the immense building at night. Mr. Chadwick, once of Willard's, Washington, is manager, and Mr. E. J. Baldwin, Pacific coast millionaire, owner and proprietor. The hotel and furniture cost about $3,500,000.

The London Stock Exchange dates from the South Sea bubble, and was in its origin an association for the protection of dealers in stocks, who were gamblers in the eye of the English law. A motion has been brought before Parliament for a Royal Commission to enquire into its "origin, object, present constitution, customs, and usages."

Says an Eastern writer: "Contracts for several new hotels have been awarded in Paris, all of which are to be finished in time for the great exhibition next year. French architects have been sent to this country to get ideas and plans, and it is more than probable that some of the new caravansaries will have American proprietors or managers. It seems to be tolerably well understood abroad that Brother Jonathan knows how to keep a hotel."

Advices from the International Commission of European engineers and scientists, now engaged in actual survey of the proposed Darien route for a ship canal connecting the Atlantic and Pacific, say they will complete the work about the 1st of April. They also indicate that they have found the low pass hitherto rumored to exist, within the State of Panama and will report in favor of that route as much more favorable than any others hitherto examined by any engineers.

There is great hope for iron manufacturers and locomotive builders in what is going on in the Southern Hemisphere, particularly in Australia and Brazil. The need of railways in Australia has been seriously felt, and in South Australia alone the Government proposes to spend $10,000,000 in constructing them. Nearly 100 lines of railroad are now building or under survey in Brazil, and in this country, as well as in Australia, American rails and rolling stock are in high favor. Orders for locomotives for Australia have recently been received in Paterson, N. J., while Russia, also, has ordered a number of cast iron car wheels for trial on the road from Moscow to Odessa.

The excitement in Essex county, Massachusetts, over mining is very great. Several new mines are to be opened, and one at Amesbury is soon to be vigorously worked. At Merrimack a shaft has already been sunk 250 feet, and there are five levels, with indications of an immense amount of vein matter still below and beyond and the quantity in sight is estimated at 400,000 tons, besides a rich deposit of gray copper discovered. Several veins of quartz were recently encountered, which are found to assay $20 to $25 per ton in gold and silver. All the land-owners in the region have already grown wealthy in anticipation.

At the meeting of the trustees of the Cincinnati Southern Railroad, held recently, the contract for the construction of the bridge across the Tennessee river was awarded to Clark, Reeves & Co., of Philadelphia, over six other competitors. The contract price is $117,000. The bridge will be an iron Whipple truss bridge, 1,804 feet long, and will cross the river in Hamilton county, about five miles northeast of Chattanooga, near Boyce's station. The superstructure will rest on eight piers and the abutments on either side. A draw, to be operated by hand and steam, will form the third span from the north end of the bridge, the round pier being 612 feet from the north shore. The distance from low water mark to the top of the cross ties will be 64 feet. The contract calls for the completion of the work by the 1st of January, 1878.

The second test of the West Side Pumping Works engines, of this city, has not yet been made, partly because the builders of the engines have not completed all arrangements for the test, and partly because the city is in no hurry to have it made. Preparations are being made slowly. If the test about to be made fails to show that the engines are capable of the specified "duty"—90,000,000 foot pounds—and the builders desire any further trial, they will be obliged to pay for it. The city has, already stood a $6,000 expense for the first trial, and will pay the cost of the second, but will go no further, demanding a settlement upon the showing of the last test. City-Engineer Chesbrough, when spoken to about the probability of the success of the trial, said that he would not be surprised if the 90,000,000 power were shown, because he had known instances where tests made after an engine had been in operation for a year had developed a much larger duty than those made shortly after the engines had been constructed.

The constitution of Illinois at present allows the General Assembly to pass laws permitting the owners or occupants of lands to construct drains and ditches for agricultural purposes across the lands of others, but makes no provision for the payment of the expenses of such drainage, except by voluntary contributions. An amendment which is to be submitted to the Legislature provides that the General Assembly may establish drainage districts and give to the persons placed in charge of such districts the power to construct and maintain drains and ditches, and pay the expenses of the same by special assessments on the lands benefited In several parts of the State, notably in the east and south, there are large tracts of lands which at the present time are substantially worthless, but which, if drained, would produce good crops. The amendment is one which is not likely to meet with any opposition, and the only regret is that it is necessary to delay the enactment of a law for the benefit of owners of such lands until the constitutional amendment has been adopted by the people.

It is stated that the Board of Army Engineers, consisting of Generals Duane, Wright and Gilmore, who were ordered to examine the Washington Monument and the foundation upon which it is bullt, after a careful examination of the work already done, in examining the strata beneath the foundation, ordered further work to cease. All the members agreed that the monument could not be completed according to the original design, because the foundation will not admit of more weight. The foundation was originally placed eight feet below the surface, and is now settled eight and three-fourth inches. The settling began while the monument was building, and as in settling the shaft leaned north, the builders still built according to the plumb-line, and the whole pile is crooked. The Board directed Gen'l. Q. A. Gilmore to prepare a report. He will suggest that the present weight of the shaft is all that the ground will bear. The report will be made to the commission appointed by Congress, of which the President is chairman, some time this week. This confirms the opinion of Supervising Architect Mullett.

RAILROAD NOTES.

The Car Accountants meet at Indianapolis, April 18th.

Work has been begun by Abbott & Co., on the Eastern Extension Road of Nova Scotia.

Capital stock to the amount of $50,000 has been subscribed in Racine, Wis., to build a street railway.

It is proposed to build a railroad from West Lebanon, Ind., westward to the C., D. & V. R. R. at Alvin, Ill.

Surveys of the Burlington, Keosauqua & Western R. R. Iowa, are to be made at once.

The grading of the road bed of the Philadelphia and Atlantic City R. R. is activley progressing.

The following new companies have been incorporated: St. Louis Fort Scott & Northwestern R. R. Co., place of business, Fort Scott, Kansas. Florence, El Dorado & Walnut Valley R. R. Co.; place of busines, El Dorado, Butler county.

The American Railway Master Mechanics' Association meets at St. Louis, May 15th.

The Master Car Builders' Association meets in Cleveland, June 13.

The Joliet Construction Company is negotiating with the Keokuk, North and South R. R. Company to build it to Mount Pleasant and Iowa City. A meeting of the two companies was held recently, which will doubtless result in placing the line under contract.

The name of the St. Louis, Rock Island and Chicago R. R. has been changed to the "St. Louis Division of the Chicago, Burlington and Quincy R. R."

Walker, Clark & Roberts of New York, the contractors of the Nova Scotia, Nictaux, and Atlantic Central R. R. will begin work May 1st. The road is 65 miles long.

Judgment has been given in the Saginaw Court, Michigan, against the Chicago, Saginaw & Canada R. R. Co., in favor of Thos. M. Nelson of Chicago, contractor, for $5518.18, and Thos. M. Nelson & Co. contractors for $18,057.50.

The railway from Vera Cruz to the city of Mexico is nearly 268 miles long, has many fine iron bridges and 18 lengthy tunnels. It cost the round sum of 40,000,000 of Mexican dollars, and is held to be the finest constructed railway on the American continent. Its greatest elevation above the sea at Vera Cruz is 13,000 feet.

A. A. Robinson, chief engineer of the A., T. & S. F. road, with a full corps of surveyors, commences work at once. The road will be fully completed to El Dorado on or before the middle of July. Col. Thomas Nickerson, who is now in Florida, has given instructions to Superintendent Morse to put this road through to El Dorado as soon as possible.

It is proposed to extend the Kansas Central (narrow gauge) R. R., from a point near Winchester, Jefferson county, via Oskaloosa, Topeka, and Council Grove, to Great Bend, Barton county. Meantime the direct line will be pushed westward from Holton through the northwestern portion of the State, with Denver as its ultimate destination.

A company has been formed for the entensive building of narrow guage roads. Mass meetings have been called in Ottawa, Saline, McPherson, Harvey, Sedwick, Butler, Greenwood, Woodson, Allen and Bourbon counties, to be held commencing March 15th, and ending April 3rd. The intention is to agitate the question, and induce aid by bonds under the amended law passed at the last session of the legislature.

The sum total of railway lines through the principal countries of the world now reach the distance nearly fourteen times the circumference of the globe, or one and one-half times the journey to the moon. Of this total the United States lines extend 75,585 miles; Great Britain at home and through her foreign domains, 66,101; Russia, in Europe and Asia, 34,914; those of France, 30,779; and of the German Empire, 18,799.

ARCHES;

CONSIDERED GRAPHICALLY.

[Copyright 1877.]

(*Continued from page 66.*)

41. Let us consider the two cases of a horizontal beam and of one inclined to the horizon at an angle i; it is known, from the usual formula for deflection, that, other things being equal, the deflection of a beam is directly proportional to the load and the cube of the length. If then the inclined beam is of a length l, and the horizontal one of a length $l \cos i$, as shown in Fig. 8, the deflections of each, measured perpendicularly to the respective beams, will, as regards length of beam only, be in the ratio of l^3 to $l^3 \cos^3 i$. But, if each carries the same load W, the transverse component of W, which alone causes flexure of the inclined beam, the longitudinal component producing direct compression, will be W cos i; whence the deflections perpendicular to each beam will, for similar points, be proportioned as 1 to $\cos^3 i$. And again, the vertical component of the deflection of the inclined beam will be to the perpendicular amount as cos i to 1; whence the *vertical* deflection of the inclined beam will be to that of the horizontal beam of the same

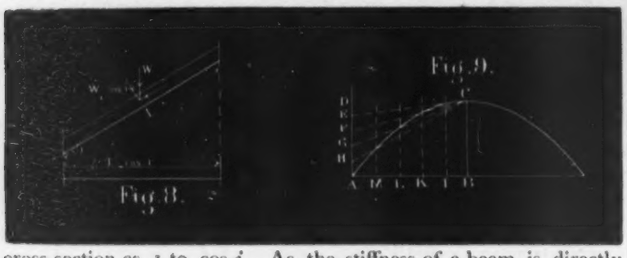

Fig. 8. Fig. 9.

cross-section as 1 to cos i. As the stiffness of a beam is directly proportioned to its breadth, should the inclined beam be made broader in its horizontal dimension than the horizontal beam, in the ratio of 1 to cos i, the depth being unchanged, the *vertical* deflections of the two beams for the same load would be exactly the same.

42. Any very small portion of an arch, taken within such narrow limits as to be considered straight, behaves like the inclined beam as regards its flexure under a load, and therefore it follows that, if an arch has the dimension perpendicular to its face increased, from the crown to the springing, in the ratio of the secant of the inclination to the horizon, it may be discussed as if it were a beam of uniform cross-section, of the same span, similarly supported, and carrying the same load which produces flexure. In the arch some of the load does not produce flexure, as in the parabolic rib, before cited, a uniform horizontal load gives equilibrium. We propose, in our analysis of the parabolic rib, to make this supposition, that the rib is broader at the abutments than at the crown in the ratio just mentioned, and thus to simplify the work of investigation. Iron arches whose flanges or chords are thicker as we approach the springing, in the above ratio, while the perpendicular depth between the two flanges is constant, practically satisfy this case. In this class of ribs the intensity of the direct thrust on the square inch will be the same at all cross-sections.

43. As we desire the reader to reproduce, on a much larger scale, the figures and problems for himself, it will be best to give an easy method of constructing a parabola for an arch, or for a curve of equilibrium for a complete load, uniform per foot of span. If A B, Fig. 9, is the half span, and B C the rise of the desired parabola, whose vertex will be at C, draw A D, perpendicular to A B, and equal to B C. Divide A B into any convenient number of equal parts, and divide A D into the same number. Draw straight lines from C to the several points of division of A D. The point where C E cuts the vertical from I, the one where C F cuts the vertical from K, C G that from L, and so on, will be points in the desired parabola.

44. Taking up then the case of the parabolic rib, hinged at the ends only, let us place a single weight at the point I, Fig. 10. If the lines A C B fulfil the condition of §11, that the sum of the products of the ordinates D E and E F for all points of the arch equals zero, or

$$\Sigma\, E F . D E = 0, \qquad (4.)$$

A C B will be the required curve of equilibrium. From the reasoning of §42, it will be proper to divide the areas above the springing line A B by equidistant vertical lines, moderately near together, scale off the quantities corresponding to E F and D E, and find the proper position of A C B by one or two trials. It can be thus located with all desirable accuracy, as a slight movement of the point C vertically alters the quantities to be computed very materially. The reader who is not familiar with the higher mathematics can thus verify the results we are about to obtain.

45. Since C G may be considered the unknown quantity, by which to locate A C and B C, the one condition of equation (4.) will readily give it, and its exact value can be determined by the integral calculus.

Let the half span A K = K B = c; the height or rise of the arch at the crown = k; then if K G, the distance from mid-span to

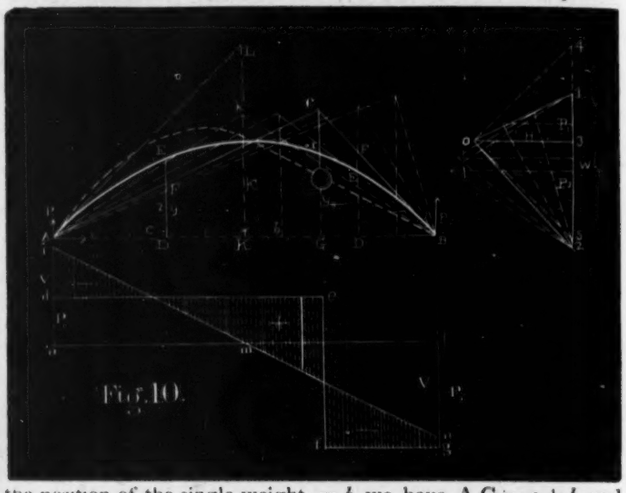

Fig. 10.

the position of the single weight, = b, we have A G = $c + b$, and G B = $c - b$. Let the required maximum ordinate C G = y_0. Let A D, the distance from the abutment A to any ordinate D E, between A and G, = x. Since the ordinates to a parabola from the line A B are proportional to the product of the segments into which they divide the span, we have

$$D E : k = x(2c - x) : c^2, \text{ or } D E = \frac{k}{c^2}(2cx - x^2).$$

$$\text{Also, } D F : y_0 = x : c + b, \text{ or } D F = \frac{y_0}{c+b}\, x.$$

The required condition is that

$$\Sigma\, E F . D E = 0, \text{ or } \Sigma (D E - D F)\, D E = 0;$$

therefore,

$$\Sigma\, D E^2 = \Sigma\, D F . D E. \qquad (9.)$$

Substituting the values of these lines from above, and writing the sign of integration, we get for the left hand member,

$$\int_0^{2c} \frac{k^2}{c^4}(2cx - x^2)^2\, dx = \frac{k^2}{c^4}\int_0^{2c}(4c^2x^2 - 4cx^3 + x^4)\, dx.$$

$$= \frac{k^2}{c^4}\left(\tfrac{4}{3}c^2x^3 - cx^4 + \tfrac{1}{5}x^5\right)_0^{2c} = \tfrac{16}{15}k^2c. \qquad (10.)$$

For the right hand member, between A and G, we get

$$\int_0^{c+b} \frac{y_0}{c+b}\, x . \frac{k}{c^2}(2cx - x^2)\, dx = \frac{k\,y_0}{c^2(c+b)}\int_0^{c+b}(2cx^2 - x^3)\, dx$$

$$= \frac{k\,y_0}{c^2(c+b)}\left(\tfrac{2}{3}cx^3 - \tfrac{1}{4}x^4\right)_0^{c+b} = \frac{k\,y_0}{c^2}\left[\tfrac{2}{3}c(c+b)^2 - \tfrac{1}{4}(c+b)^3\right]. \quad (a.)$$

For the portion between G and B, if we write $c - b$ for $c + b$, and reckon x from B to the left, D F will equal $\frac{y_0}{c-b}\, x$, while D E will be unchanged; so that the integration for the right hand member of (9.), between G and B, and between the limits $x = 0$ and $= c-b$, will give

$$\frac{k\,y_0}{c^2}\left[\tfrac{2}{3}c(c-b)^2 - \tfrac{1}{4}(c-b)^3\right]. \qquad (b.)$$

These two portions, (*a.*) and (*b.*), for the right hand member of (9.) being added together, will produce, when the terms with the odd powers of b are cancelled,

$$\frac{k\,y_0}{c^2}\left(\tfrac{5}{6}c^3 - \tfrac{1}{6}cb^2\right).$$

Finally equate this value with (10.) to satisfy (9.) and

$$\frac{k\,y_0}{6c}(5c^2 - b^2) = \tfrac{16}{15}k^2c; \qquad \text{or}$$

$$y_0 = \tfrac{32}{5}k\,\frac{c^2}{5c^2 - b^2}, \qquad (11.)$$

which is the desired value of C G in terms of the constant quantities and the variable distance K G. This expression is plainly applicable to points on either side of K.

If $b = nc$, where n = a fraction of the half span,

$$y_0 = \frac{32}{5(5 - n^2)}\, k, \qquad (11'.)$$

a quantity independent of the span of the arch.

(*To be continued.*)

LOSS OF THE STAFFORDVILLE DAM.

Having arrived at the season of the year when the rapid melting of the snow combines with the spring rains to smell the watercourses, we expect to hear of rivers overflowing their banks, mills stopped by backwater, and more or less damage and inconvenience caused by freshests. But we did not look for the recurrence of a type of disaster which we have twice within a short time had occasion to regret. The breaking away of the dam at Staffordville, Conn., on the 27th of March, was the occasion, by the flood of water let loose, swelled by mill ponds in the Willimantic River below, whose dams also gave way, of the destruction of property in mills bridges, dams, houses, merchandise, railroads, etc., to the amonnt of some $300,000. Fortunately the loss of life was very small, owing to sufficient warning, and perhaps from this circumstance, or because the public is becoming used to such tales, the accident has excited but passing notice in the papers.

We have not been able to harmonize the several accounts to our entire satifaction, but can give some facts which will probably be of interest. The dam was on the east branch of the Willimantic River and was the property of a Reservoir Company, composed of owners of mills on the stream below. The reservoir was about a mile and one-quarter long and averaged a quarter of a mile wide; the dam, standing in a gorge of the stream bed, was about twenty-feet high at the deepest point of the valley, previous to this last fall, when it was raised six feet, and in length the main portion was perhaps 150 feet, a short dam. The front of the main dam was composed of masonry, four feet thick at the top and ten feet at the bottom in the middle, the front of the well being laid of rough stone in cement and the back of the same dry, while the middle of the wall was composed of broken stone and boulders without cement. The wall was backed by gravel and earth, and it is stated that when the additions were made last fall, this material was put in in a frozen state, so that it was not consolidated. At each end of the dam proper, which was built on a curve, was a wing of earth thirty feet thick at the base and fifteen feet thick at the top, which was built in the early winter, the earth being banked up in freezing weather. The wings seem to have been the weakest portions. It is also stated that a large cast iron waste pipe four feet in diameter was introduced for the purpose of carrying off the surplus water. The water in the reservoir had never before been allowed to rise to the full height of the dam since it was raised, but the recent storm brought in so large a body of water that the level could not be kept down. A leak showed itself on Monday; workmen endeavored all that day and the following night to stop it. It seems to have occurred at the waste pipe, and finally, on Tuesday morning, gained so rapidly upon the bank that the waste pipe was shot out of its place and the breach was fairly made. The west wing of earth was thus rapidly eaten away, letting out the flood of water which carried off several dams in succession below. About 100 feet of the stone dam and the other wing of gravel is still standing at the east and north side of the break. Is is apparent, therefore, that the main portion of the dam, while perhaps rather poorly constructed, resisted the pressure, the failure occurring at the west wing, and a small portion of the main door being washed out as the flood hurried past the unprotected end.

We are inclined to attribute the breaking away to the percolation of the water, under the increased head, along the waste pipe, through earth not properly consolidated. The location of conduits and pipes through the body of embankments has been the cause of the failure of a number of dams otherwise sound. It will be remembered that such was practically the cause of the giving way of the Lynde Brook Reservoir last year,—lack of protection to the culvert or arch for the pipes. It is acknowledged by all to be a sound principle never to carry a pipe through an embankment, especially if new, if it can be avoided, and if one must, to hinder, by all possible means, the water from following along the side of the pipe. Any body which offers a continuous line for the guidance of a thread of water is dangerous, and the slightest settlement, which cannot be avoided with new filled earth, will open a crack along the pipe for the percolation of water, in the place most difficult of access. Wide flanges at intervals, jogs or counterforts of masonry, etc., are some of the precautions to be introduced.

It is possible, however, that the earth bank which composed the wing that was carried away failed independently of the portion adjoining the waste pipe. It is stated to have been very poorly and hastily put together, of earth more or less frozen, and therefore to have been ill adapted to withstand any head. It is highly probable that the owners expected to prevent the wings from being tested as they were, by keeping the water down.

It is very natural that such an accident, within a year from that near Worcester, should arouse the general press to cast a fling at engineers. But no one of our profession seems to have been called in to advise about, plan, or superintend this construction, and therefore we are not to be held responsible for the penny-wise economy of those men who add to and patch up a dam as they think best. Whether these repeated lessons will do any good to people at large is a question. The general public will not be likely to be any more cautious in the future, when they indulge in ignorant experimenting in this branch of engineering, than were this company of Staffordville mill-owners who, with the Lynde Brook disaster fresh in their minds, put a contractor to work late in the fall, to raise their dam and increase its head. We can, however, reap a certain advantage by the study of these cases of failure, and it is possible that some of the projectors of new works of this nature may be led to think, that true economy will dictate the employment of the best means in their power to make a dam safe, and that the advice and co-operation of an engineer who has made such subjects his special care will be well worth to them whatever they may cost.

THE Mill River disaster of May 16, 1874, when $1,000,000 worth of property was destroyed and 140 lives were lost by the sudden emptying of 114 acres of water into a narrow valley, and the accident at Lynde Brook, near Worcester, Mass., March 30, 1876, where a water-works reservoir gave way, as described in the NEWS at the time, causing damage to property of nearly an equal amount, but drowning only one person, recur naturally to our readers on hearing of this failure of a dam. In both of the above cases the structures were faulty in original construction.

WE have to announce that the proposed book on the Ashtabula Bridge accident edited by J. M. Goodwin, C. E. of Cleveland, O. will not be published at present, as the support accorded to Mr. Goodwin in the way of subscriptions was not sufficient to warrant him in incurring the great cost of publishing the book as he proposed. We regret this the more as there is no doubt that the book if published, would embody the greatest amount of valuable information on the subject of iron bridge building that would be extant in this country. We had the satisfaction of personally inspecting the manuscript and also the drawings, and we then thought that the subscribers would be very fortunate in securing such a work for the price asked, which, after the very lowest prices for labor and material were obtained both in Cleveland and Chicago, was barely sufficient to cover the cost of the proposed edition, without allowing the editor anything for his services. Mr. Goodwin is entitled to the thanks of the profession for the labor and money which he has expended in his attempt to present the official record of this noted accident to his fellow engineers, and we regret that his enterprise was not more widely appreciated.

PLATE No. IX of Sanitary Engineering was the last one issued; there will be about eight more and we will publish them as speedily as we can conveniently and *economically*. We publish this week a copy of specifications for a sewer in New York City, which we think will serve as a model for similar documents where they are needed.

CIVIL ENGINEERS' CLUB OF THE NORTH-WEST.

The 74th regular meeting of the Club was held at the Sherman House Club Rooms, Chicago, on Tuesday April 3rd, President Chesbrough in the Chair.

After approval of the minutes of the preceding meeting the Secretary reported the following donations to the library:

From Gen. A. A. Humphreys, Chief of Engineers U. S. Army—"Report of a Reconaissance, from Carroll, Montana, to the Yellowstone National Park and return; by Wm. Ludlow, Captain of Engineers.

From Chas. Paine, General Superintendent of Lake Shore and Michigan Southern Railroad—Report of miles run by passenger equipment wheels for three years.

Pamphlet—The M. S. & N. I. R. R. Co. *vs.* Samuel H. Turrill—Brief for Appellant.

From United States Lighthouse Board — Memoir upon the Illumination and Beaconage of the Coasts of France.

Wm. Sooy Smith, C. E. read a paper upon "New methods of making iron and steel, with a letter from Mr. A. T. Hay, of Burlington, Iowa, supplementing it with remarks and replies to questions put by many of the members present. By request Gen. Smith then read a description of the process of rust or oxidation in iron, and the new method of protecting it by aid of superheated steam.

The Secretary gave the particulars and details of the proposed trip to New Orleans at the invitation of the American Society of Engineers. The Illinois Central Railroad Company will furnish free transportation available to and from New Orleans to members of the Club.

The report and discussion upon the Metric System was postponed, and the meeting adjourned.

THE RANSOM STEAM STREET CAR.

As the subject of the application of steam to the propulsion of street cars is attracting considerable notice, and as we have referred, in our issue of March 10, to the Ransom Steam Street Car which has been introduced upon the Market street railway, of Philadelphia to a limited extent, we have extracted from the correspondence of the *Railway Review* a description of this car and engine, as built by the well-known manufacturers, Gilbert, Bush & Co., of Troy, N. Y.:

"Mr. Ransom has given many years study to the subject, and has finally attained success. Some two years ago Gilbert, Bush & Co. being convinced that Mr. Ransom's theory was a correct one, agreed to build an experimental car, which was tested on the different roads of Troy with success. It was afterwards exhibited in various parts of the country. It is called the "Pioneer" car, and has run 12,000 miles. None of the working parts show the least indication of wear. This car is now in the shops being refitted for running on the West Troy & Albany street railroad. A company has been organized, styled the Ransom Steam Street Car Co., with E. G. Gilbert, President. The company have in the shops four cars nearly completed, part of an order of six for Philadelphia, two of which have been shipped. The cars are models of beauty, resembling the drawing-room car. From the outside they appear longer than the ordinary street car. The inside of the car is richly finished; various kinds of woods are used, mahogany, walnut, rosewood and silver maple panelings. Heavy cushions are used, and cushioned seat backs. The car is lighted by an exceedingly brilliant silver-plated reflecting center lamp. The roof is similar to the modern steam car, or what is called the raised roof, running from end to end, with ventilator over the doors. The car is warmed by steam-pipes running the whole length. The boiler is upright, and encased in a wooden jacket It is made of the best charcoal hammered iron, and will resist a pressure of 500 pounds to the inch, while the pressure need not exceed 120 pounds. The escaping steam is passed through a two-way valve out of the smoke-stack and a muffler without making the slighest noise. The action of the wheels is the only noise heard when the car is in motion. The car cannot by any chance escape from the control of the engineer, as the brakes can be operated either by steam or hand. The lever moved a certain distance comes in contact with an automatic arrangement which, at the will of the engineer, tightens or releases the brakes. The engine is 20-horse power, and is hidden from sight in a dust-tight box made under the car floor, and independent of the car, being supported by the drive-wheels and an arm suspended from a cross beam. The whole is accessible by means of trap doors. The distributing valves are in the cylinder heads, giving a steam port of ⅞ inch. The cylinders are 5¼ inches in diameter and 14 inch stroke. When the engine is in full gear the steam will follow the piston 10 inches and exhaust at 12½ inches. The pump is under the car body at the rear end (inclosed), and can be got at from the outside by lifting lids. The tank is under the rear end of the car, and by means of a hole through the car above the wheels, hose may be introduced into the tank at any street hydrant and a supply of water obtained. The tank will hold 130 gallons of water, enough to run it 15 miles. There are two sand boxes under the seat, capacity half bushel each. One oiling a day is sufficient, as all the working parts have oil cellars. The total cost of running this car is $7 per day, and it is capable of doing the work of four horse cars. A street broom and scraper are attached to the car truck, which clears the track of snow or mud. The cars are about evenly balanced, and ride as easy as any horse car when empty and easier than the horse car when loaded."

ENGINEERS AS RAILWAY SUPERINTENDENTS.*

BY JOHN B. JERVIS, C. E.

Now, it may be said, why all this about the superintendency of a railway—engineers are not much engaged except in construction? My object is to show that an engineering education fits a man best for the superintendence, no less than for the construction of a railway. I regard it an error that the profession has not given more attention to superintendence of operations. It demands the same thoughtful analyzing mind, to operate, that constructs. I have presented this case to impress the importance of employing the best engineering experience and ability in the superintendence of railways. The case is a plain one. Say, management has failed to pay interest, and the railway was sold by foreclosure of mortgages. An engineer takes charge, and in 2¼ years this is all changed and the property becomes a success. But why an engineer? A true engineer first of all, considers his duties as a trust, and directs his whole energies to discharge the trust, with all the solemnity of a judge on the bench. He is so immersed in his profession that he has no occasion to seek other sources of amusements, and is therefore always at his post. He has no ambition to be rich, and therefore eschews all commissions that blind the eyes and impair fidelity to his trust. His ambition is to make his trust a success to the proprietors. His education fits him to analyze facts, and more successfully than a layman to produce the best results of administration. To reach the best results of railways, they must be put under the superintendence of competent engineers.

It may be inquired, why should not engineers seek to be rich? certainly, they need the benefit of pecuniary resources as well as others, which is not denied. *Rich* is a relative term. The man who, by proper economy, is able annually to lay something by as as an investment from his earnings, is only exercising the prudence necessary to provide for age or infirmity. This all men should do, and it is especially important for an engineer, and by this means his mind may be at ease in regard to the future. What is meant by a thirst to be rich, is a speculating turn of mind, which is sure to prevent any especial eminence in an engineer. He should be careful to secure a proper salary, and then give his undivided attention to the duty he assumes. I have known several engineers who were always on the alert for speculation, but I have not known one such to secure any valuable standing as an engineer. To this it may be said, engineers have not, in all cases succeeded in conducting the operating business of railways. The same may be said of lawyers, or any other profession, and it is just as important that the party in interest select a competent and faithful engineer as a competent lawyer. The same discretion is necessary in one case as in the other.

Being now past four score years of age, I can have no other motive than the public good in the above remarks. I make them in view of much personal experience, which has brought me to the conclusion, that the railway and kindred public works will not realize their legitimate benefits until their supervision is committed to competent engineers. In order for this, it is necessary to cultivate the profession so as to secure the qualifications and character before named, to carefully avoid all theories that are not based on well established and thoroughly analyzed facts, and to be very cautious before applying any theory, to see that all the facts involved are obtained, and that none are hastily and inconsiderately assumed. The profession is one of great importance to the public interest, and no pains should be spared to fully qualify those who pursue it for every engineering emergency, and to fit them for the discharge of every duty with scrupulous fidelity.

The table below shows the prices paid for water in the following German cities using water meters:†

City.	*Price per cu. meter. (1000 liters)*	*Price per 100 gallons.*
Altona	5 3-10 cents.	2.00 cents.
Berlin	1⅞ to 7½ cts.	0.71 to 2.84 "
Braunschweig	1¼ to 2 cts.	0.48 to 0.75 "
Bochum	1 3-5 to 2½ cts.	0.63 to 0.95 "
Cassel	1⅝ to 2¼ cts.	0.61 to 0.95 "
Carlsruhe	1⅞ cts.	0.71 "
Cologne	1¼ to 2½ cts.	0.48 to 0.95 "
Danzig	2 1-10 cts.	0.75 "
Dortmund	2 1-10 to 2½ cts.	0.75 to 0.65 "
Dresden	3 cts.	1.14 "
Dusseldorf	1⅝ to 2 cts.	0.61 to 0.76 "
Eisenach	3¾ to 6¼ cts.	1.42 to 2.37 "
Essen	1 7-10 to 2 1-10 cts.	0.63 to 0.75 "
Frankfort	1 7-10 to 2½ cts.	0.64 to 0.95 "
Freibourg	1¾ cts	0.66 "
Halle	1 7-10 to 2 7-10 cts.	0.63 to 1.02 "
Kiel	2½ cts.	0.95 "
Leipzig	2¼ to 2¾ cts.	0.85 to 1.04 "
Magdeburg	1⅝ to 2 cts.	0.61 to 0.80 "
Posen	2⅞ to 3¼ cts.	1.09 to 1.28 "
Stuttgart	3¾ to 5 cts.	1.42 to 1.93 "
Wiesbaden	2½ to 6¼ cts.	0.95 to 2.37 "
Witten	1¼ to 2½ cts.	0.48 to 0.80 "
Vienna	2 4-5 to 5¾ cts.	1.06 to 2.00 "

Average, 2.748 cts. per cu. m., 1.041 cts. per 100 galls.

ON THE PROBABLE ERRORS OF LEVELING; WITH RULES FOR THE TREATMENT OF ACCUMULATED ERRORS.*

BY WILFRED AIRY, B. A., M. INST. C. E.

TABLE II.—AVERAGE DIFFERENCES in a SINGLE MILE DUE to GROUND of VARIABLE INCLINATION—COMPUTED from the RESULTS of TABLE A. by the FORMULA.

Prob. Diff. = $\sqrt{}$Mean of squares of diffs. due to the several slopes of ground.

Character of the ground.	Average Difference in a single Mile. Great Britain.	India.	Switzerland.
	foot.	foot.	foot.
(1) "Level ground," in very favorable circumstances of weather. Example.—A broad level valley or margin of a lake	.0230	.0142	.0125
(2) "Gently undulating ground," where the gradients rarely, if at all, exceed 1 in 100. Example.—Most of the roads in India	.0238.	.0168	.0148
(3) "Steeply undulating ground," where the gradients rarely, if at all, exceed one in 20. Example.—Most of the roads in Great Britain	.0316	.0189	.0166
(4) "Mountain roads," where the gradients rarely, if at all, exceed 1 in 10 Example.—The mountain roads in Switzerland	.0416	.0254	.0224
(5) "Very steep and rough ground," where the gradients frequently exceed 1 in 10, and the leveling is carried over mere road tracks or paths	....	....	.0416

NOTE.—Quantities in black partly estimated as per Table I.

Having thus determined the 'average differences' from the results of standard leveling in different countries, it remains to form a table of the probable errors due to those differences. The proper method of doing this will be found in the "Theory of Errors of Observation," art. 60; and from the formulæ of that article it can be shown that if there be two independent measures of the same quantity the probable error of each measure is 0.477 × difference of the measures, and the probable error of the mean of the two measures is 0.337 × difference of the measures. With these coefficients it is easy to frame a table of probable errors applicable to the cases of lines which have been leveled once or twice.

C. THE TREATMENT OF PROBABLE ERRORS IN THE CASE OF A COMPLEX SYSTEM OF LEVELED LINES.

This is illustrated by working out in detail an example showing the application of the theory of probable errors in adjusting the levels of a number of points connected by lines of leveling on the 'polygon' system, the closing error of the chief polygon being 0.286 foot.

* From the Proceedings of the Institution of Civil Engineers, London.

Let A B C D E F G A be the polygon system (Fig 2), of which all the lines have been separately leveled.*

TABLE III.—PROBABLE ERRORS of the RESULTS of SINGLE or DUPLICATE LEVELING on GROUND of DIFFERENT CHARACTERS, FORMED from the RESULTS of the SWISS LEVELING.

Character of the Ground. (For Definitions, see Table II.)	Average Difference in a single Mile of Two Observers (see Table B)	Probable Error in a single Mile of each Observer. Multiplier = .477.	Probable Error in a single Mile of the Mean of Two Observers. Multiplier = .337
	Foot.	Foot.	Foot.
Level ground	.0125	.0596	.0421
Gently undulating ground	.0148	.0706	.0499
Steeply undulating ground	.0166	.0792	.0559
Mountain roads	.0224	.1068	.0755
Very steep and rough ground	.0416	.1984	.1403

The lines B C, C D, C F, and F G have been leveled twice each, and the remaining lines once. The length in miles, and the character of the ground, are written against each line.

The first thing to be done is to form a table of the probable errors of the several lines from Table III. If a line has been leveled once only, the probable error in a single mile, is to be taken from the third column of Table III; but if twice, it is to be taken from the fourth column of the table, and applied to the mean of the observed results.

With these probable errors the equations of the determination of the levels of the points A, B, C, D, etc., can be formed, in the most probable manner, in accordance with the method of 'least squares.' The final results, together with the effect of the corrections, are shown in Table V. The heights are measured from datum-level 500 feet below the point A.

Thus the effect of the corrections is to raise the points B and C a little, and to lower E, F, G, and A′ considerably. This seems consistent with the nature of the ground, which from A to D is favorable, and the corrections are small. From D through E and F to G the distance is long and the ground rather steep, and it is accordingly on these lengths that the corrections are heavy. At the same time the cross lines B G and C F, though short, are steep, and would well allow of the

* The polygon system of the example, with the lengths of the lines and the observed levels of the several points, is taken from an actual case in the "Nivellement de la Suisse." The description of the ground is not given in the "Nivellement," and is to some extent hypothetical.

Fig. 2.

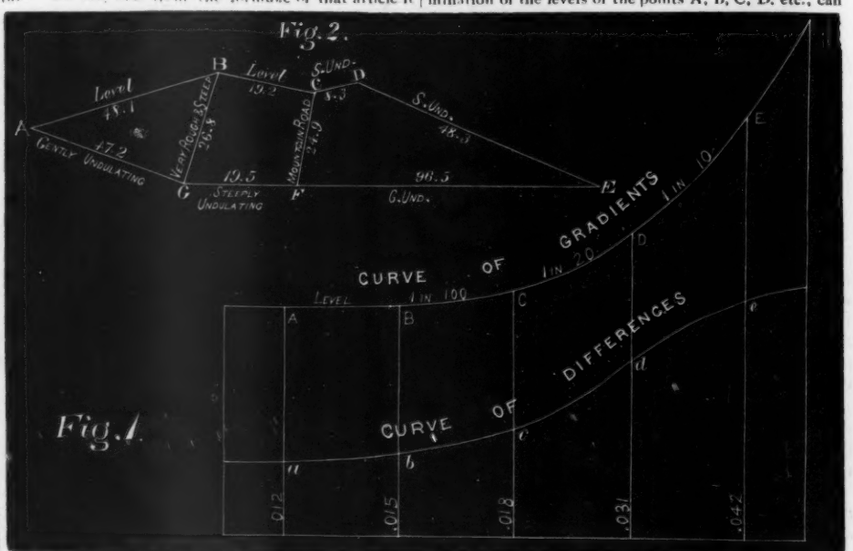

Fig. 1.

heavy corrections required by the corrected levels of G and F. The final correction to A is of course the closing error of the polygon, as shown by the observed levels.

TABLE IV.
PROBABLE ERRORS of the LINES A B, B C, C D, ETC.

Section.	Observed Difference of Level of the two ends of the Section.	Character of the Ground.	Number of times Leveled.	Length of Section.	Probable Error in a Single Mile, from Table C.	Probable Error of the Section = Probable Error in a Single Mile × √Length in Miles.
	Closing Error = .286					
A B	Feet. 193.458	Level	Once	Miles. 45.1	Foot. .00596	Foot. .041
B C	15.860[1]	Level	Twice ...	19.2	.00421	.018
C D	699.887	Steeply Undulating...	Twice ...	8.3	.00559	.016
D E	—1322.470	Steeply Undulating...	Once	48.3	.00792	.055
E F	955.880	Gently Undulating...	Once	96.5	.00706	.069
F G	155.125[1]	Steeply Undulating...	Twice ...	19.5	.00559	.025
G A	—607.454	Gently Undulating ...	Once	47.2	.00706	.048

do do A.	500.286	500.000	— .286

D. REMARKS ON THE INSTRUMENTS AND METHODS OF WORKING USED IN ACCURATE LEVELING.

For the Standard leveling in Great Britain, India, and Switzerland, Y levels were used. This construction offers facilities for the quick and accurate determination of the collimation error and the level error. Its chief disadvantage is that, from want of rigidity in the mounting, it sometimes happens that the internal tube (which carries the object glass) does not slide truly in the external tube, so that the optical axis does not keep constant in position when focussing the telescope. This defect is remedied in part by Mr. Gravatt's construction, which, however, introduces inconvenience in respect of the collimation adjustment. In the instruments used for the Swiss leveling the spirit-level is movable, and is clipped upon the telescope tube—a construction which has no apparent advantage. In the English and in the Indian instruments the spirit-level is always attached to the telescope. In some levels recently constructed for foreign governments by Messrs. Troughton and Simms, the spirit-level is attached to the frame which carries the telescope, instead of to the telescope itself; by this arrangement the level is more firmly secured and less liable to accident.

Table VI contains the essential information relating to the instruments and staves used in the initial leveling of different countries.

In the Swiss leveling the distances were always measured by taking the reading on the staff of two fixed wires in the diaphragm of the telescope, and corrections were afterwards applied with much labor in respect of all the instrumental errors due to the difference of distances. In Great Britain and India the distances were always chained equal.

In India Colonel Walker discovered that the instruments had a tendency to settle on their axis between the reading of the back and forward staves. This would tend to produce a cumulative error, and he has therefore established a rule of alternating the order of observation at successive stations of the instrument, by reading the back staff first at one station and the forward staff first at the next. The special necessity for this appears to be mainly due to the practice of unshipping the instruments at every station for removal to the next station. To counteract the cumulative error originally noticed by Dr. Whewell, which is introduced by leveling a line continuously in the same direction, all the lines of the initial leveling in Great Britain were leveled both ways from end to end. In India the same end is gained by splitting up the long lines into short sections of 4 or 5 miles in length, and leveling alternate sections in opposite directions. But no precautions appear to have been taken in the Swiss and French leveling to guard against these accumulated errors.

Errors may easily be caused by an inaccurate method of placing benchmarks. Thus it has been usual in England to cut benchmarks deeply on the vertical faces of walls, and from the inconvenience of ascertaining the exact level of the center of the mark, it is easy to make at once an error as large as would be generated in a considerable length of leveling. In the Swiss leveling the benchmarks were always defined by bronze bolts let into a horizontal face.

DEFECTIVE SEWERAGE.

The subject of defective sewerage is now agitating the public mind and awakening a degree of serious and thoughtful interest that indicates the full realization, at last, that the evil is one fraught with immediate danger to the health and life of our citizens. The peril is one that threatens all alike and in meeting and treating which the entire community can have but a common interest. And, as a matter of course, the very first measure of safety, the first step toward the practical remedy of existing defects as well as the sure prevention of like defects in sewers to be laid hereafter, is to get at the cause of the trouble already experienced. And here are some facts bearing upon the subject which ought to aid in the solution of this problem of public safety. In the first place, there are now and always have been men in this city calling themselves sewer-builders, and having licenses for doing sewer work, who are totally unfit for the business, and as long as such men are granted licenses our citizens must endure the consequences of defective sewerage. Another point is that there is now for sale in the city an enormous quantity of what is termed cull or No. 2 pipe, which, in order to secure trade even among those with whom its defective character is a matter of notoriety, is sold at very low figure. This cheap pipe is not only of a very poor quality in respect to soundness, but is made from a coarse fire-clay which will not vitrify, and, although it may be hard burned, it still remains as porous as a sponge, utterly incapable of standing the acids and gases of sewers any more than a common drain tile,—notwithstanding all which, unless careful scrutiny is exercised by those in authority, this miserable pipe will still be laid in spite of all practical vigilance on the part of inspectors. And here is still another very important point which has not yet been presented to the public, and that is the growing tendency to use socket pipe in the place of ring pipe, which has always been used without exception, until within the last two or three years. There are serious objections to the use of socket for the reason that it is extremely difficult to form a close connected joint on the under side of the pipe and in case (as so frequently happens) it is not well cemented and made permantly tight the liquid matter from the sewer soon works through, emitting its unwholesome stench and leaving in the sewer the heavy deposit of matter which soon obstructs the circulation and leads to the necessity of cleaning out. It is a pertinent fact, too, that there is nowadays twice the amount of sewer cleaning over that required at an earlier day, when only ring pipe was in use. As yet there has not been a foot of socket pipe laid in the main sewers of the city, and if ring pipes are best adapted for main sewers, it is reasonable to infer that they are best for private sewers, and the time has come when the welfare and the safety of the community requires that this matter of defective construction and improper material in sewer-building should be seriously and thoughtfully dealt with.—*Chicago Times.*

WATER SUPPLY OF EUROPEAN CITIES.

While Glasgow has tapped Loch Katrine and Manchester and Liverpool have gone to the Cumberland or Welsh lakes for water, London is compelled to pump and strain Thames water and choke while drinking it. This Spring the water is more unwholesome than ever, owing to the disastrous floods of the Winter. It is yellow and turbid, thick with the washings of the acres that have been overflowed, discolored by the chalk of the Berkshire and Oxfordshire hills, and filled with fungoid growths and moving organisms. Under these circumstances the Metropolitan Board of Public Works has taken steps to improve the water supply, and by buying out the existing companies to put the water works under municipal management. Rate-payers will not listen to the proposition to resort to other sources of supply, such as the head waters of the Severn, and London will have to drink contaminated water for many years to come. The filter beds used by the companies can be cleaned and repaired, and new wells can be sunk in the chalk northeast of the city, but these half-way measures are not likely to afford permanent relief. Not only is the water unwholesome; there is not enough of it.—*N. Y. Tribune.*

NOTES.

Three bridges were swept away between Amherst and Northampton, Mass., by the freshet.

Work on the proposed new postoffice at Pittsburgh, Pa., will shortly begin.

The new Court Theatre is being built in Vienna at a cost of $2,500,000.

The bridge over the river at Saco, Me. has been closed to travel, being pronounced unsafe.

Reports from Conway, N. H., state there is an immense volume of water there.

The pipe lines in the oil region, Pa., have consolidated and are managed by one board of directors.

The Cincinnati Southern R. R. bridge over the Kentucky river is said to be the highest in the world.

The Waterworks Commissioners, of Toronto, Ont., purpose erecting a new reservoir at a cost of $175,000.

GEN. O. S. BABCOCK has been assigned to the charge of the Fifth Light House District, with headquarters at Baltimore, Md., relieving Major Franklin Harwood.

Alderman Joseph Brunet, contractor and trader, of Montreal, has made an assignment for the benefit of his creditors. His liabilities are about $150,000.

The water is now being put in the West Branch canal, Pa., from Lock Haven down. The Williamsport level and mill ponds are filling, and navigation will be open early.

The Saco river is rising rapidly. The saw mills are all shut down. The river above Saco is a solid mass of ice, which, if it should start now, would cause much damage.

The stonecutters in the employ of Mr. Davis, contractor for a portion of the Lachine Canal Works, Montreal, Canada, struck for an advance of wages, their demands having been refused.

The Harbor Commissioners, of Quebec, are applying to the Dominion Government for an additional sum of $250,000, which is required to ensure the carrying out of the harbor improvements. Mr. Varret has been elected Secretary of the Commission.

Reports from Maine indicate that the rivers are very high. Some damage has been done and more is anticipated. Seventy feet of Moulton's stone dam on the Big Togus River, near Gardiner, were swept away this afternoon, causing a loss of about $2,000.

The Susquehannah river at Pittston, Pa., owing to the eighth inch fall of snow which succeeded the heavy rains

lately, has swollen to an alarming extent. Continually rafts of logs and timber have been floating past, and should the river continue to rise it will no doubt do some damage to property in the Wyoming Valley.

The Connecticut river at Bellow Falls, Vt., has risen considerable lately, the heavy and continuous rains having had the effect to swell all the streams and rivers. Large quantities of floating ice, logs, lumber and stumps have passed rapidly down stream. The river is still rising and fears are entertained of a disastrous freshet in the Connecticut valley.

The engineers appointed by the Niagara Suspension Bridge Company to examine and report upon the state and stability of the bridge have completed their duty, and reported to the effect that the bridge is entirely safe for the transit of regular trains such as have hitherto-fore used it. The commission consists of W. Milnor Roberts, chief engineer of the Northern Pacific Railroad; T. E. Sykels, chief engineer of the Union Pacific Railroad, and W. H. Payne assistant engineer of the New York and Brooklyn Bridge. It is understood that a further report from these gentlemen is promised in a few days, giving tests, with drawings, and the reasons in detail for the opinion expressed.

About as startling a proposition as has yet been devised by modern engineering is the scheme gravely advocated by the Liverpool *Post* to block up the Straits of Belle Isle. The object is to divert the passage of the ice which now comes down every year from Baffins Bay, through the Straits, and makes the shores past which the icebergs float many degrees colder than those to the eastward that face the ocean and get the benefit of the Gulf Stream. It is believed that, if the project could be carried out, the entire climate of Anticosta and of the Gulf of St. Lawrence would be largely modified, and navigation through the neighboring waters could be kept open during the whole year. In the narrowest portion the width of the Straits is eight ond one-half miles.

A contract was awarded to Messrs, McLees & Co., of Twelfth and West streets, New York, for manufacturing 140 tons of galvenized anchor bars, for the last series of bars, for the bridge. The cost is to be one cent per pound.

LOCOMOTIVE ENGINEERS.

An important step has just been taken by the directors of the Philadelphia & Reading Railroad Company. It is a declaration of open war against the Brotherhood of Locomotive Engineers, the protective organization of the trade. The directors have issued an order to all the employees of the road denouncing the Brotherhood and announcing that the engineers in the employ of the company will in a few days be called upon to decide "under which king" they will serve, threatening discharge to all who refuse to leave the Brotherhood. What the ultimate effect of this order will be cannot be foreseen, for the Brotherhood will not be likely to yield without a struggle.

The order is as follows:—

"PHILADELPHIA & READING RAILROAD COMPANY,
OFFICE NO. 227 SOUTH FOURTH STREET,
PHILADELPHIA, *March 27, 1877.*

Mr. ———, Locomotive Engineer:—

DEAR SIR.—In view of the recent high handed interference with the business of railroad companies, and the serious and sometimes fatal consequences that have resulted to the innocent traveling public from the unjustifiable and arbitrary conduct of the organization known as the Brotherhood of Locomotive engineers upon other railroads, it has been deemed unadvisable to retain in the employment of this company any one who is a member of that organization.

If you are in such membership you will be called upon in a day or two to decide whether you desire to remain in the employment of the company by complying with the regulation requiring you to withdraw from the association referred to.

It is not the desire of the company to deprive its employees of any of the beneficial or life insurance features of the Society of the Brotherhood of Locomotive Engineers without offering in their stead greater benefits of a similar character; and it is therefore proposed by the company to establish and endow a life and accident insurance fund, out of which all engineers, upon payment of a monthly sum less than previously paid, will receive, in case of accident or death, greater benefits than those heretofore derived from the Brotherhood of Locomotive Engineers.

Upon being informed of your desire to continue in the employment of the company the undersigned will be pleased to give any information you may desire as to the details of the beneficial fund, and to discuss with you directly any question involving your relations with the company.

Respectfully yours.

J. E. WOOTEN, *General Manager.*"

Upon the recommendation of Engineer C. C. Martin a contract was entered into with the Brady Manufacturing Company, of Plymouth street, Brooklyn, N. Y., for making 120,000 couplings for the bridge cables. The material is to be furnished the contractor, who is to manufacture the coupling required at the cost of four cents a piece.

NEW METHODS OF MAKING IRON AND STEEL—A LETTER FROM MR. A. T. HAY—WITH AN INTRODUCTION BY WM. SOOY SMITH, C. E.*

Without assuming to endorse a process for making iron which is just beginning to challenge our attention, I desire to present it for the consideration of the members of the Club; believing that a careful study of a whole family of metallurgical processes which seem to grow out of one fruitful invention cannot prove unprofitable to us.

Much of the popular ignorance respecting iron and steel results no doubt from the error of regarding iron as iron and steel as steel, instead of the alloys which they really are, differing widely in chemical constitution and physical properties.

The quality of any particular sample of iron or steel depends, first, upon its chemical composition, and, secondly, upon its mechanical structure. Starting with identity of chemical composition, it is practicable to secure uniformity in mechanical structure. But so strong are the affinities of iron for the various substances which enter the ores, fluxes and fuel employed in its manufacture, and so variable are these affinities under the necessary thermal conditions, that heretofore it has been exceedingly difficult to so control them as to secure uniformity in the product. This fact has been painfully evident to the civil engineers of the country who have been charged with the construction of bridges, roofs, machinery, etc., upon the strength and durability of which large numbers of human lives depend.

A few of the iron makers of the country have, by long and faithful effort and under the most favorable circumstances as to the materials available, succeeded in making brands of iron which command general confidence. But up to the present time it has been exceedingly dangerous to rely upon the irons and steels sold in open market. Perhaps undue attention has been devoted to a single series of iron compounds, namely, that resulting from its union with carbon in various proportions.

More recently iron and steel have been studied with reference to the compounds of iron with other substances, such as manganese, silicon, chromium, aluminum, nickel, etc., and with the most important and promising results. One investigator, Mr. A. T. Hay, now asserts that by using a sponge which he is able to produce by means of a magnetic furnace, he can so perfectly control the action of the affinity of iron for other substances as to cause it to unite with those which he supplies to it in this sponge and thus produce a class of most valuable iron compounds with absolute certainty.

He claims to have thoroughly investigated the electrical relations that subsist between iron and the other substances isomorphous with it at the various temperatures required in the production of those compounds, and that by attention to these relations he secures the compounds desired. His processes are now in course of thorough practical demonstration, and an iron is produced by them at the Wyandotte mills which is said to equal if it does not excel the best Swedish iron in softness and toughness. Tons of this material are now on sale in this city, similar to the specimens which we have the pleasure of examining here this evening. And be it remembered this is but one of a large class of products which the inventor claims to be able to make by his process. Indeed there is scarcely any of the ordinary desirable characteristics of iron which he will not undertake to impart and at a trifling increase of cost.

A method which promises so much in the production of excellent iron and steel for our use cannot fail to interest the genuine civil engineer, and the attention of the Club is therefore invited to the following letter describing it, which was written by Mr. Hay, by request.

General Wm. Sooy Smith, Chairman U. S. Commission for testing Iron and Steel, Chicago, Ills.

DEAR SIR: In response to your request, I will state: Iron is not found to any extent in native masses, but in ores mineralized by different elementary metals and substances in a state of oxides, carbonates, etc., and with many of these elementary metals, it is isomorphous, and when revived to a metallic state, they alloy or combine with it in variable proportions. It is upon these alloys or combinations that depends its real value. Iron chemically pure, is neither desirable nor practical, it being too soft for mechanical purposes, besides it has a great affinity for oxygen, at ordinary temperatures, and rapidly corrodes and wastes away. The isomorphous group to which iron belongs consists of fourteen elementary metals, six of which are electro negative to iron and seven are electro positive to it, at ordinary temperatures. Two of these are pyro electric and change polarization toward iron under thermic conditions at a cherry-red heat, and three give their electricity to iron above 90° Fahrenheit, and take it away from it below that temperature. That is, iron alloyed with its regular electro positive elements will be fibrous or granular and strong, and not seriously affected by cold; and an alloy with pyro electric elements will render the product "red short," but tough and fibrous when cold. And any combination containing electro negative elements, to an extent that the iron becomes the most positive element in the alloy, will render it "cold short," crystalline, and brittle with a powerful affinity for phosphorus, sulphur, etc. Such iron will be tough when hot, but become weaker and more brittle as the temperature falls below 90° Fahrenheit. There is a well known chemical law that governs the effect of the sulphur, phosphorus, etc., upon iron products. Two bases are never taken to form a double salt from the same isomorphous family group; hence, if iron becomes the electro-positive element in any given alloy, the metalloids will combine with it alone, and the product will be bad, while on the other hand if the iron is rendered the electro-negative metal in any given alloy, then the poisonous metalloids will combine with the more positive elements, and the product will become malleable, ductile and tenacious. In a word, it will be fine iron. Swedes iron, so celebrated throughout the world for its fine qualities and steel properties, is assimilated in its ores *only* with the isomorphous elementary metals of the *electro-positive* series. Out of hundreds of assays of Swedish ores examined not one contained any of the isomorphous elements of the *electric-negative* series, (save and except copper and cobalt, and these were very rare). See Sweden's iron report for 1876. Besides iron and carbon, fine carbon steel also invariably contains two or more of these electro-positive elements, including traces of phosphorus and sulphur.

Under thermic conditions it will be found that some of the electro-negative elements assume the positive and give their electricity to iron, while other negatives become electro-positive to iron and protect it from acidulous influences, practically revealing the fact that the best alloy for iron will depend entirely upon what it is wanted for. The most valuable alloy to resist compression, stress and strain at ordinary temperatures is not the best adapted under the thermic conditions, nor will either of these be suitable under acidulous influences. Therefore, without having regard to the chemical, electrical, pyro-electrical and thermic relations that exist between iron and the members of its own family, including the effects and affinities of the metalloids upon the various combinations, it is utterly impossible to give what we call iron any definite quality; and observing these relations it is practical to make iron and steel of any given character and quality absolute and certain. Hence any tests of iron and steel founded upon ordinary merchant bar in stock, will be comparatively of but little value so long as we remain in ignorance as to what they contain, and are unable to reproduce metals identical in constitution to those tested. Rest assured of one thing, certain, and that is the economy, durability and safety of all iron structures depend upon these isomorphous combinations. These principles and facts are all made manifest and practical under the Hay metallurgic processes, which relate to the manufacture and use of a ferruginous alkaline sponge, that may contain severally or combined, beginning with iron and aluminium, any other one or all of the regular isomorphous metals of the electro-positive series, including one or more of the alkalis proper, and for certain qualities of iron requiring a high resistance to heat and acidulous corrosion. Metals from the electro-negative series may be incorporated in the sponge, which is prepared from the oxides, clorides, fluorides, etc., as found in nature, by means of a magnetic furnace having from four to six electrical zones, whereby those refractory oxides, etc., are easily reduced in combination with silica to a silicious-metalic mat or sponge, which is fusible at a bright red heat; and when introduced into the puddle or forge fires the metals therein chemically combine in stock. It is also a deoxidi ing and a desulpurizing agent and a perfect welding flux that renders high steel as weldable as iron at a glowing white heat, with a decided improvement in quality of product over the original stock. Thousands of tons of cast steel have been faggoted and rolled into wire rod at the Harrison wire works, St. Louis, of which Thomas W. Fitch (late of the United States navy) is president, and William L. Reynolds superintendent. It also renders practical, a stratified (iron and steel) boiler plate, adding tensile strength, and in such a combination, under thermic conditions, the steel becomes the electro-positive metal, and protects the iron against corrosion. The sponge has already become a saleable product, and at this time commands one hundred dollars per ton, and five per cent. thereof is sufficient to make "fine iron" out of Iron mountain, of Missouri, Lake Superior, Tennessee and other good pig irons. The process is not a single process involving but a personal or individual interest, but a metallurgic family of processes, with a broad principle underlying them as essential to successful iron manufacture as the principles of agricultural chemistry are to successful farming. No genuine advance in the manufacture of iron and steel is possible (except by accident), if their constitution and the means of imparting it are lost sight of.

These processes underlid all true iron metallergy, and therefore deserve early, thorough and exhaustive examination and investigation on the part of all practical investigators. Respectfully submitted to your consideration. I am, sir, very respectfully yours,

A. T. HAY.

BURLINGTON, IOWA, February 19, 1877.

* Paper read before the Civil Engineers' Club of the Northwest, April 2, 1877.

THE MULTIPLICATION OF INDUSTRIES.

One cause which has been assigned for the stagnation of industries felt during the past few years has been over-production. All manufactured articles were put upon the market in greater quantities than the demand called for, and consequently the time soon came when prices were lowered. We can make more iron, more paper, cotton, cloth, shoes, sewing machines, mowing machines, railway cars, etc., than we can use. The stimulus of the excessive call for certain classes of articles at the time of the war is thought to be answerable for the result. However this may be, the fact remains that we have experienced a long stoppage of the wheels of industry, although now an encouraging revival and a call for manufactured products seems to have already begun. The market which has been opened to our wares abroad we have alluded to before, and, in addition to the articles then spoken of, we notice that shipments of American glassware have been made to England, which are said to compare favorably with the best English glass, in color, finish and the power of resisting changes of temperature.

But it was not in this direction that our thoughts were turning to-day. If some branches of industry are crowded, and the capacity for production is beyond the present consumption, it behooves us to enlarge the scope of our labor by taking up and fostering other branches which have been much neglected. There are doubtless many manufacturing operations which can be carried on to advantage in places where the raw material, coal or power, labor and the means of living are cheap, which have heretofore been left to other countries. Employment would thus be given to many hands at present idle, and a field would be opened for the use of capital which now is unimproved. The lines of investment in railroad bonds and kindred securities are closed by reason of public distrust, arising from a remembrance of past experience, and therefore legitimate and properly secured projects in manufacturing, initiated and prosecuted with due discretion, ought to be able to command such capital as may be needed.

Our success in new directions in recent years should be an encouragement to other undertakings, and those manufacturers who can turn their attention and their machinery to operations which are nearly allied to the old ones, so that the machinery can be easily adapted and the former experience be serviceable in the new pursuit, will be most likely to find the change profitable, and be able to give work to waiting laborers. Thus mills which produced cottons have been turning their attention to finer grades and to cotton and wool goods; woolen manufacturers are producing alpacas and dress goods. It needs only a brief mention to recall our successes in several directions. We formerly purchased all our watches abroad; now we turn out a native product which, by the aid of most exact and ingenious machinery, averages better than the imported article, and we are encroaching on the foreign market; American silks have made a place for themselves within a few years, and our sewing silk rivals that of Italy in quality and cheapness. There appears to be no reason why we should not make our own linens, growing our own flax, of which we imported last year $17,000,000 worth. We can make our own pottery and ornament it. Our art schools and classes in industrial design will make us independent of foreign decorators. We can rival Sheffield in cutlery, if we please. The *Journal of Commerce*, of St. Louis, says, "We are still importing $7,000,000 of iron and steel, some $10,000,000 of leather and goods; $22,000,000 of silk goods; $4,000,000 of soda and salts; $10,000,000 of tin plates; $35,000,000 in woolen goods, amounting" with flax, hemp cotton goods, china and glass ware, "to nearly $250,000,000 annually paid out by our people to foreign nations for their labor, and this, not because we are better employed in making something to a better advantage to exchange for it, but because we are a new nation and have not yet developed these industries in our midst."

The *American Manufacturer* has been urging the expediency of making the tinplate in this country which we now import in large quantities, and a recent writer sets forth the cost of the materials and labor required, with an assurance that a handsome profit can be realized. He states that "the adaptation of American iron for tin plate in tenacity, and surface, cannot be surpassed, and, when intelligence and economy are practiced in its manufacture, it will be more remunerative than any other branch of the iron industry."

The editor of *Scribner's Magazine*, writing upon this topic urges its importance very strongly "Out into these fields the capitalist must reach or find no profitable employment for his money. Into these fields labor must go, or lie idle and descend into pauperism. It is not a matter of choice with us, it is a matter of necessity. Of course it will take a good many years to accomplish the results we seek. There must be costly experiments; there must be processes of education of head and hand; there must be time for capital to move itself; but the change must come, and towards these fields the public attention should be immediately directed. Our only hope for steady and permanent prosperity lies exactly here. We must produce for ourselves, and thus employ the nation's idle capital and idle hands, and the quicker the movement is made, and the more efficiently it is prosecuted, the earlier our old and much longed-for prosperity will come back to us. The subject is full of interest, and crowds the coming century with changes and developments which the most hospitable imagination must fail to measure."

While we still feel that a gradual revival of our industries has begun which will surely lead to prosperous times, we also feel that it behooves us to enter upon the cultivation of some of the new fields which lie open to individual or corporate enterprise.

We notice that iron sleepers are said to be on trial on a portion of the Central Pacific Railway, with satisfactory results. Their description, as given in the *Railway Age*, is as follows:—

"They consist of circular concave plates, sixteen inches in diameter, with a saddle upon the top in which the rail is set, much as in the ordinary chair. The outer half of the saddle is cast with a plate or bed-piece, and the inner half is secured with bolts after the rail is in place. An iron cross bar connects the plates on opposite sides, the bar having a joint in the center held by a bolt, with an elastic material in the joint. Elastic material is also placed between the rails and the bed-plates."

These sleepers appear to be much like ones used by English engineers in India with good results. The bowl is made large enough to give the desired bearing on the ballast, which, in the English sleepers, is, we believe, tamped through two holes at the sides and their form gives great strength. Where wooden sleepers are expensive, from scarcity of timber, they may compete with the more perishable material, but the experiment with iron sleepers in some parts of India was tried because ants were so destructive to wood. In the number of the NEWS for February 17, page 44, will be found the statement of Mr. Higinbotham in regard to their employment in India.

We have felt moved to make but one remark in regard to the method of discussing a bridge truss, as set forth by our correspondent on page 75, of the number of the NEWS for March 31, and that is rather of the nature of an inquiry. But in the first place we would say that, as he undoubtedly agrees with us in regard to the final or resultant forces on each portion of the truss, it is not so much matter how far he carries a stress round if he only brings it finally upon the right piece, and secondly, as at any section we must have equilibrium between the stresses in the pieces cut by the section and the external forces on one side of such section, the ordinary equations of statics will give the desired stresses in each panel without regard to their paths elsewhere. A graphical diagram drawn by Clerk Maxwell's method, will indicate by simple inspection how individual loads tend to change the stresses in the braces, and will show that the final stress is the algebraic sum of the partial stresses. And, finally, we know that our original answer was considered satisfactory by the engineer who propounded the query.

But to our remark:—As our correspondent has, in his second figure, brought 6000 lbs. of steady load upon the left abutment through the first brace; as he states that stresses cannot pass up compressive members, and that horizontal members cannot carry a vertical force, (by Proposition 6 and 4); and as he states that 7200 lbs. of live load, if now placed at the lower end of the first vertical, will all go to the left abutment,—how does he get the extra 1200 lbs. of dead load, as he thinks, off from the left abutment on its way to the right abutment where it is needed?

THE Water Works "Crib" was inspected on Wednesday the 11th inst., Captain Falcon, the diver, examining the portion below the surface of Lake Michigan, and notwithstanding the alarming predictions of a certain engineer, the structure was found to be as free from any indications of dissolution, or even from damage, as when it was erected. A detailed report of its condition will be given on this Saturday, and any points of general interest we will give to our readers next week.

WE are reminded by our reference to the Brooklyn Theatre fire of our thoughts as we were slowly making our exit from McCormick Hall on the occasion of the Ole Bull Concert a short time ago. We give it as our personal opinion that in case of a fire in McCormick Hall in this city, and its ensuing panic, that not one person in ten would escape, and we do not believe that even that proportion of those in the gallery would escape. We do not know how a worse exit could be arranged, except it be a genuine labyrinth.

No country in the world can compare with this in genuine "sensations," but at what a fearful sacrifice of life and property we are earning our most unenviable reputation. The burning of the Southern Hotel at St. Louis is the most recent in the long list of terrible calamities that incompetence, ignorance, recklessness or carelessness have inflicted upon the American public. A theatre represented to be "perfectly safe," with the most ample means of escape which architectural skill could devise, proves to be a fire trap from which there was really no escape; an iron bridge on the model road of the country turns out to be devoid of every principle of safety, and the horrible scenes at Ashtabula are the results, and now comes the story of the inmates of a great hotel awakening, not an hour after midnight, to find themselves surrounded by flames, and all escape from death cut off. In the name of humanity what was the interior construction of the Southern Hotel that in two hours it should be consumed; what kind of service also did its proprietors give to their guests that at that early hour of the night smoke and flames could roll through the corriders and halls to gain such headway that escape was impossible to the wretched tenants of the upper stories? What next, and whose turn will it be to pay the penalty of American greed for money?

A REGULAR meeting of the Chicago Chapter American Institute of Architects was held April 5, 1877, at the rooms of the Treasurer, 85 Dearborn St. The minutes of the last meeting were read and approved. The proposed amendment to Section 4, Article IV of the By-Laws was taken up and passed by a unanimous vote.

Mr. James R. Willett then read an illustrated paper entitled "Perspective by Scale."

Mr. Bauer made some interesting remarks on Architectural Education, which gave rise to discussion which was participated in by the members generally.

On motion, adjourned.

HENRY L. GAY, *Secretary.*

Written for "Engineering News."

REMARKS ON THE SLOPE OF SOUTH PASS, AND A PART OF THE LOWER MISSISSIPPI RIVER.

BY MAX E. SCHMIDT,

Ch. Asst. Eng. South Pass Jetty Works.

Ever since the commencement of the Jetties at the mouth of South Pass (June 18th, 1875) the engineers in connection with the works considered it highly important to possess some reliable information relative to the elevation of the water-surface of South Pass at any point of its length, and at different stages of the Mississippi River and the tides. Unfortunately, for want of time, this information could not be obtained previous to the construction of the works that are now erected at the head and at the mouth of the Pass. Many phenomena which occurred under the agency of these works, might otherwise have been explained, whereas without previous knowledge for over a year the field was open to conjectures and suppositions.

The distance between the head and the mouth of the Pass being about twelve miles, with banks chiefly extending over marshy grounds, leveling was looked upon

as an undertaking almost too delicate to be tried, except at extreme low river, when the soil would possess stability enough to support the leveling instrument. Moreover the rich growth of reeds, which skirt the Pass on both sides, being particularly impenetrable at the little ridge or natural levee, close to shore, which would be the path the leveler would select, the leveling itself was thought of only as a "*dernier resort*."

Having so many difficulties to contend with, and so little time to spare, another method had to be substituted, a brief description of which will be given below, and only recently, and aided by exceptionally low water, a line of levels was successfully run on the west bank of the Pass. The results of both observations are before us, developing many interesting data.

The first observations were made without a level at least without the instrument we call "level." Owing to the low stage of the Mississippi, the hydrostatic conditions of the Delta had reduced the slope of the river below New Orleans practically to a horizontal plane, on which the small tides of the winter season would fluctuate, causing a perceptible inland current, when the tide would come in, and slight flow out after the tide had turned. How very little resistance the current of the Mississippi River offered to the ingress of the tide was determined by simultaneous gauge-readings, made at the mouth, the head of South Pass, and at Quarantine Station, 37 miles above the mouth, where the same fluctuation to a tenth of an inch was recorded at precisely the same time.

Under these conditions then it was only necessary to consult the action of the tides a few days in advance, and choose the time of the Moon's least (0) declination, when the tides are known to be smallest and stationary, thereby to avoid the application of too great a correction, and mark the elevation of the water-surface at a given time on stakes previously driven along the Pass, while tide-gauges were being observed simultaneously at several important places.

At South Pass additional precautions were taken to insure correctness. The stakes were driven every mile commencing from South Pass Light House up and down stream; the circles on the diagram represent the location of the stakes. At the same time tide-gauges were placed at A, B, C, D, E, F, G, H, I and K, those in the Pass (A, C, E, G,) being connected by careful leveling with the corresponding ones in the bay (B, D, F and H). Above the head of the passes, at the jump, quarantine and New Orleans, gauge-readings were also noted.

The value of the observations to be made, depended now solely upon the weather, a calm clear day, and the greatest possible elimination of the tides being absolutely necessary for an even adjustment of the Gulf-level and the water in the bays to the east and west of South Pass. On a calm day, at low river, especially after a long series of calm days, and at a time when the moon's position keeps the tidal wave off this shore, it can be claimed that for all practical purposes the levels of the two Bays and those of the more remote portions of the Gulf are in equilibrium. Therefore, as long as the alluvial banks are tight enough to hold the volume flowing in the Pass, and as long as there is no knowledge of a percolation or any other hidden subterraneous drainage, there is no reason why not to accept the difference of readings of two gauges, A and B for instance, as the fall between point A and the Gulf of Mexico. The levels run afterwards proved this to be correct.

The smallness of the dimensions dealt with, when attempting to obtain a figure for the slope of South Pass, is the only one great difficulty in arriving at correct results by any other mode than leveling. What at the Upper river could justly be overlooked as being equal to a mere "fraction of an error" becomes of considerable importance here where the slope is reduced to as insignificant a figure as one or one-half inch per mile.

The observations were made with great care four times, January 9th, 19th, 20th and March 28th, of the present year. On the first date the weather was not favorable, but the results proved satisfactory on the others.

It was at first the intention to mark the water-surface at all the "mile points" simultaneously; but, as this would have necessitated quite a corps of assistants, the marking was done as fast as possible with a steam-launch starting from the head of the Pass down, and stopping at every "mile-point" just long enough to drive a nail, where the water-surface would indicate it at that moment. The tide-gauges being read in the meantime every ten minutes, at the points described above, enough data were obtained to construct the slope of the Pass for the precise time, when a nail was driven, and any correction that had to be applied, could with facility be taken off from the plat itself.

The zero, which appears on the profile of slopes, and to which all elevations are referred, is the plane of "Average Flood Tide," as determined by the U. S. Engineers for the works at the mouth of the Pass. Knowing the height of each nail above this plane, gauges could now be set with their zero at the same elevation, and the difference of readings on these gauges would indicate the fall in the Pass from one mile to another.

However, before definitely setting the gauges, it was decided to run a line of levels between one or two of the "mile-stakes," as a check on the elevation of the nails. Under considerable difficulties this line of levels was finally extended over the entire distance from the head of the Pass to Port Eads, and thence over the

9 " "	0.715	0.715	.715	0.781	—0.066

The two comparative slopes in the diagram represent the descent of the Mississippi, *exclusive of tidal influence* from New Orleans through South Pass into the Gulf. The flat slope occurred on January 19th, when the Mississippi at New Orleans was 15½ feet below high water mark of 1874, and the steep slope on March 28th when the river at New Orleans was within 7.8 feet of that high water mark. Attention is called to the sudden declination in slope, caused by the increased volume being forced into the defiles, created by the works at the head and the mouth of South Pass. It is obvious, that while passing through these works, the regimen of the Pass is disturbed, but it is also evident that the steep sope indicates the certainty of a very substantial enlargement of section by scour, yet to be effected, before the equilibrium throughout the Pass will be regained. That the latter process is daily advancing you have already heard through Mr. Corthell's letter, published in one of your last issues.

In conclusion, the following table showing the rate of fall, as a guide to the diagram, may be of interest.

TABLE SHOWING RATE OF FALL PER MILE BETWEEN THE MAIN STATIONS FROM NEW ORLEANS TO THE MOUTH OF THE JETTIES, JAN. 19, AND MARCH 28, 1877.

AMERICAN SOCIETY OF CIVIL ENGINEERS.

The Ninth Annual Convention of the Society will be held in New Orleans, Tuesday, Wednesday and Thursday, April 24th, 25th and 26th next.

Sessions for the consideration of professional subjects, and one for the transaction of regular business, will be held at the Chamber of Commerce (on Common Street), beginning at 9½ o'clock A. M. Tuesday, and continued on Wednesday.

It is proposed, on Thursday, to visit objects of interest in and about New Orleans, and to have the Convention dinner at 7½ o'clock that evening; on Friday and Saturday, to inspect the jetties at the mouth of the Mississippi, stopping on the return at the orange groves and at some of the sugar plantations; and on Monday to go to the Bonet Carre Crevasse.

A trip to Galveston (by steamer leaving New Orleans, Wednesday, May 2d), to visit that city and the United States works there, is also proposed.

In accordance with the rules governing Conventions, a list of topics to be considered at the regular sessions is submitted, with references to the Papers treating these subjects, published in Transactions since May, 1876.

I. BRIDGES.

CXXXVII. The Failure of the Ashtabula Bridge. C. Macdonald. March.

CXL. Approximate Determination of Stresses in the Eye Bar Head. W. H. Burr. April.

II. HYDRAULICS.

CXXV. On the Failure of the Worcester Dam, a Report. T. G. Ellis, Chairman. July.

CXXVI. Cut-offs on the Mississippi River, their Effect on the Channel, above and below. C. G. Forshey. September.

CXXX. Efficiency of Steam Vacuum Pumps. J. F. Flagg. December.

CXXXI. Principles of Tidal Harbor Improvements, as applied at Wilmington, Cal. C. B. Sears. December.

CXXXVI. A Water Conduit under Pressure. J. T. Fanning. March.

CXXXIX. Consumption and Waste of Water delivered by Public Works. J. H. Harlow. April.

Report of Committee on Gauging of Streams. J. J. R. Croes, Chairman. To be called for.

III. MASONRY.

CXXXIII. Reconstruction and Enlargement of the Cork Run Tunnel, on the Pittsburgh, Cincinnati & St. Louis Railway. M. J. Becker, January.

CXXXIII. Notes on Masonry of the East River Bridge. F. Collingwood. January.

Report of Committee on the Nomenclature and Classification of Masonry. J. J. R. Croes, Chairman. June, and to be called for.

IV. RAILROADS.

CXXXVIII. On the Form, Weight, Manufacture and Life of Rails, a Report. A. Welch, Chairman. October.

CXXIX. A Cheap Transfer Table. W. P. Shinn. December.

CXXIV. On Railroad Accounts and Returns. W. P. Shinn. June.

Report of Committee on Uniform Accounts and Returns of Railroad Companies. W. P. Shinn, Chairman. November, and to be called for.

Report of Committee on Resistances of Railway Trains. W. P. Shinn, Chairman. To be called for.

V. STRENGTH OF MATERIALS.

CXXVII. Qualities of Iron and Steel. W. Metcalf. October.

CXXXIV. The Rate of Set in Metals Subjected to Strain for considerable Periods of Time. R. H. Thurston. January.

Report of Committee on Tests of American Iron and Steel. W. S. Smith, Chairman. November, and to be called for.

VI. MISCELLANEOUS.

CXXXV. A Memoir of American Engineering. J. B. Jervis. February.

CXXXVIII. Co-Ordinate Surveying. H. F. Waling. March.

Report of Committee on Metric System of Weights and Measures. C. Herschel, Chairman. To be called for.

The following are set down for

THE BUSINESS SESSION:

Report of the Centennial Commission of the Society. T. G. Ellis, Chairman. To be called for.

Report of Committee on Quarters for the Society. J Bogart, Chairman. To be called for,

The topics will be taken up for discussion in order, and members are invited to take part in person, or by sending what they would say; it is hoped that those having memoranda of experience or data relating to any of the subjects named, will present it. Papers on other professional topics are solicited, and if announced in time, their titles will be included in the Schedule to be in April Proceedings. Notice of intention to present a Paper or to take part in the discussion, should be given to the Secretary *at once.*

The Boston Society of Civil Engineers, of Boston; the Civil Engineers' Club of the Northwest, of Chicago; and the Engineers' Club of St. Louis, have been invited to attend the Convention, and to take part in the proceedings.

It is proposed that Eastern members proceed together from New York, join the Western members at Louisville, and go from there, either by rail to Memphis and steamboat down the Mississippi, or by rail direct to New Orleans The time (in hours) required will be about as follows:

New York to Louisville, rail	31
Louisville to Memphis, "	16
Memphis to New Orleans, river	36
	—83
New York to New Orleans, all rail	65

As soon as arrangements are completed, a time-table and schedule will be issued.

Head quarters of the Society in New Orleans will be at the St. Charles Hotel.

Papers on Engineering Subjects, giving results of practice, or in discussion of pertinent theoretical questions, are desired from members of the Society; their comments (whether or not present at meetings of the Society), upon papers published in Transactions, are solicited, and they are urged to contribute from notebooks and other similar records, whatever may bear upon the subjects considered, or refer to other practical topics. A list of subjects relating to the practice of engineering and its connection with kindred art and public afairs, on which papers are desired, may be found on page 51, Vol. I.

The following are the current elections, changes and corrections of members, etc.:

Additions.—Eckley B. Coxe, Drifton, Pa., February 7, 1877; William C. Gunnell, Eng. of New Capitol, Hartford, Conn., Feb. 7; Sandford Horton, 176 Franklin st., New York, Feb. 7; David E. McComb, As't Eng. on Work west of Capitol, Washington, D. C., Feb. 7.

Changes and Corrections.—Charles E. Billin, 4039 Locust st., Philadelphia, Pa.; James D. Burr, Sup't Bridge and Buildings, A. T. & S. F. R. R., Topeka, Kansas; Theodore Cooper, Office of Ch. Eng. Erie R'y, New York; Edwin A. Doane, Box 317, Meadville, Pa.; Samuel M. Gray, City Eng., 17 North Main st., Providence, R. I.; John W. Hill, Box 729, Hamilton, O.; Gabriel Jordan, Ch. Eng. & Gen. Sup't M. & C. R. R., Memphis, Tenn.; Erasmus D. Leavitt, Jr., 143 Magazine st., Cambridgeport, Mass.; William H. McClintock As't Eng. Water Works, 175 Third av., Louisville, Ky.; Cook Talcott, San Francisco, Cal.; Henry Tyson, Box 707, Baltimore, Md.; Howard W. White, 13 Revere st., Boston, Mass.; Oscar F. Whitford, Joplin, Mo.

Resigned.—John H. Sargent, Cleveland, O., February 28, 1877.

THE POINT BRIDGE.

From the Pittsburgh *Leader* of April 1st, we take the following account of the Testing of the Point Bridge:

"We are at last enabled to announce the completion of the Point Bridge across the mouth of the Monongahela connecting the lower part of Pittsburg with the South Side and Temperanceville. An informal opening took place yesterday morning, the occasion being the passage over the bridge of Mr. Jacob Painter, one of our oldest citizens and one of the largest stockholders in the bridge, accompanied by Mr. Jas. I. Bennett and a number of personal friends in carriage, among whom we noticed Mr. J. N. Mc Cullough, B. F. Jones, John Chalfant, Campbell Herron, Mark Watson, H. W. Oliver, David Stewart, Alex. Byers, Alex. Nimick and Max Moorhead.

The American Bridge company availed themselves of opportunity yesterday, through the kindness of the mill-owners of the South Side of making a test of the carrying capacity of the bridge.

After Mr. Painter and company had passed the bridge in carriages the heavily loaded teams being stationed along Carson street on the South Side, drew up a file upon the bridge. The approaches not being paved yet, and consisting of new fill, made it difficult to pull the heavy loads upon the bridge. The teams were arranged two abreast upon the bridge, a case which will never occur under regular traffic, but this was done to test the resistance of the structure to its utmost. The following statement gives the number of teams, their weight, and the total weight being at the same time upon the bridge:

	Tons.
2 six-horse teams	27
12 four-horse teams	120
1 three-horse team	8
5 two-horse teams	30
1 one-horse team	2½
2 buggies	3
25 four-mule teams	225
Weight of people on the sidewalks	60
Total weight upon the middle span	474½

This weight is equal to 12 locomotives, or to a crowd of over 7,000 people.

Altogether there were on the main span at same time 48 teams with 176 horses or mules and about 900 people.

With all this load on, the bridge deflected 4 inches in the center of the span, which is only ½ of an inch for every 100 feet of span, whereas the deflection allowed in railroad bridges is almost 1 inch for every 100 feet.

Niagara bridge, being of near the same length, deflected, when new, 10 inches under the load, and this deflection was increased in course of time to 14 inches.

The most interesting part of the test was the observation of the undulations and oscillations of the bridge under the moving load. For this purpose two level instruments and one transit were used, the levels being placed upon the piers at each end of the main span and the transit upon the south-side embankment.

The oscillations could scarcely be noticed; the up and downward movement during the passage of the load were not over one-sixteenth of an inch; the lateral motion in the center of the bridge five-sixteenths of an inch.

When one-half the span was loaded and the other half unloaded, the loaded side deflected 2¾ inches and the unloaded side was raised 1⅛ inches, which is simply due to the elasticity of the material, and proved the stiffening system of the bridge a complete success.

The designer of the bridge, Mr. Hemberle, stated that his expectations in respect to rigidity in the bridge were quite surpassed by the results. Point Bridge can certainly be claimed to be the first successfully stiffened suspension bridge in the world, and considering its magnitude, together with the design and workmanship, is and will remain a model of an engineering structure.

All the parties witnessing the test expressed their astonishment about the rigidity of the structure, and wish a lease of life for the time this structure will remain an ornament to the city.

After this was over the company repaired to Mr. Painter's office, where they were served with a sumptuous repast.

This bridge project has occupied the attention of the public more or less for many years past. The South Side embracing a large urban population, and with good river frontage for manufacturing purposes, has long felt the need of a better avenue of communication with the two cities than was afforded by the ferries. An effort was made some six years ago to more intimately connect the detached portion of this one great commun ty intersected by the three rivers by the erection of what was called the tripartite bridge—one arm resting on south bank of Ohio, another on the Allegheny bank, and the third on the Point at the junction of the Allegheny and Monongahela with the other.

Mr. Charles Davis, the consulting engineer of the present company, submitted plans for that improvement which were approved by a company formed at that time to carry out this enterprise.

The estimated cost of this work was near a million dollars.

The undertaking failed only for want of proper support from parties who were directly interested in the bridge—landholders whose property would be greatly enhanced in value by the proposed connection, had been confidently counted on.

Shortly after, an association of citizens, among whom was the present president of the Point Bridge company, applied for, and obtained a charter for building a bridge from Allegheny to the Point, known as the Union bridge, with Mr. Joshua Rhodes as president.

The work was carried out and the bridge opened for traffic some two years since.

After the opening of this arm from Allegheny, the public saw more clearly than ever the necessity of completing the connection with the South Side.

The city councils made some endeavors in this direction, but did not succeed in reaching any practical plan—the lowest figures named in this connection were about one million dollars, which, of course, precluded the possibility of success.

A few prominent citizens, believing the accomplishment of this project would be a great advantage to the city, organized a company and procured a charter. The charter dates December 26, 1874.

The directors and officers of the company are as follows: Directors—R. F. Smythe, H. Darlington, A. E. W. Painter, Henrici, Robt. Marshall, Robt. Stevenson, Joshua Rhodes, president; R. W. McConnell, secretary; Geo. Crook, treasurer; Chas. Davis, consulting engineer P. F. Brendlinger, resident engineer.

The difficulties encountered in the beginning of the undertaking can hardly be understood or appreciated by parties not directly connected with the work. The navigation interest exercised almost absolute control over the river, and was not to be conciliated by any measure short of one granting it an uninterrupted channel of the natural breadth of the river, and with head room to admit of the largest sized boats passing under the bridge at an ordinary boating stage, for manœuvering their coal fleets. With such unreasonable conditions, and with the unfavorable topography of the banks in front of the city, it was no easy problem to make a design that would not obstruct the river, and at the same time give easy grades for the approaches to the bridge. The short level on the Pittsburgh side being only 27 feet above low water, while on the south side the bank comes abrupt against the water line, with a railroad cutting its face and at an elevation of 70 feet above the river bed. The consulting engineer prepared no less than four plans to endeavor to harmonize the different conflicting interests and at the same time to get a practicable and economical construction. The president and consulting engineer of this company was before the coal exchange on several different occasions on this business; and only after several protracted interviews were they enabled to reach an agreement on the present plan. All these conflicting elements had to be harmonized in carrying out the design of and construction of the bridge.

Under ordinary circumstances bridging the Monongahela would have been of trivial importance.

The plan adopted would have necessitated an artificial approach on the north side of a depth of some fifty feet at the abutment and some six feet deep at the foot. The approach is about 1,000 feet long, and extends along the wharf outside of Water street to Penn avenue, and along Penn avenue to Point alley, giving an easy ascent to the bridge. An approach connecting the two bridges will be formed by filling up the Point. The plans for the work were approved in May, 1875.

The Point Bridge company invited bids for building the bridge in May of 1875, with the understanding that they might be for cable suspension, according to specifications and plans prepared by their consulting engineer, which called for an 800 feet middle span and two independent side spans of 145 feet each or for any other plan. Proposals were made by most of our most prominent bridge builders of the country, among whom were Roebling Sons and the Keystone Bridge company of this city, based upon various plans, viz: Cable suspension, braced arch, Ordish system, cantilever, unstiffened and stiffened chain suspension. In selecting the proper plan the directors and engineer of the Point Bridge company were well aware that their bridge was of unusual dimensions and they took care not to adopt an experimental plan. The only long span bridges in the world to compare with the requirements of the Point bridge were the Niagara railroad bridge and the Cincinnati bridge, both being wire-cable suspension, built by Mr. John Roebling, with 820 feet and 1057 feet spans respectively, and the chain suspension bridges—one the Clifton bridge over the Avon, in England, 702 feet long, and the one across the Danube at Pesth, Austria, which has a span of 666 feet—all other long span bridges being either of less length or are only built for light traffic. The plan finally adopted was a stiffened chain suspension bridge, submitted by the American Bridge company of Chicago, and designed by their chief-engineer, Mr. Edward Hemberle. This plan represents all the good features of a modern chain suspension bridge and has, in addition, a novel stiffening system, which, as far as theoretical investigations and judgment can determine, seems to obviate all the faults of wire-cables and of the formerly built chain suspension bridges.

In ordinary suspension bridges the roadway is suspended by hanging rods from chains or cables which stretch from pier to pier. In such a structure the chains or cables and the platform are flexible longitudinally, and this is shown whenever the bridge is loaded at one end more than at the other by a moving load, or is subjected to wind pressure from above or below. To improve the suspension bridges in this respect has been the aim of many engineers. The simplest improvement has been effected by keeping the points of the curved chain or cable which are more liable to deformation in their proper places by attaching them to the top of the towers by straight chains or wire-rope stays, which plan was first adopted by Ordish in Europe and by Roebling in this country.

A method for rendering the chain itself rigid has been attempted by dividing it into two parts, placed one above the other and bracing them together. A railway bridge upon this system, with a span of 260 feet, is in actual use in Vienna, in Austria, but would not be efficient for a long span. A system according to which a single chain is connected to the platform of the roadway by bracing was adopted in the construction of Lambeth bridge across the Thames in London, having spans of 180 feet, built in the year 1862, and in a footway bridge over the Main at Frankfort, Germany, of 262 feet span in 1869. This system properly improved may fulfill all the requirements to ensure stiffness; but in long spans the bracing between roadway and chains will have to be of such great length as to make it ineffective and expensive.

Mr. Hemberle's plan, as represented by Point bridge, consists of towers, chains with platform suspended therefrom in the same manner as in a regular chain suspension bridge; In addition thereto is a stiffening system above the chains, and are rigid posts arranged between chain and platform to prevent the roadway to undulate or oscillate independent of the structure above. The stiffening arrangements above the chains consist in rigid chords running in straight line from the top of the towers toward the center of the chain, and being connected thereto by a hinged joint at each end. Between these chords and the chains is a system of bracing, consisting of posts and diagonal tie-rods. All connections are pin-jointed. The chain, being a catenary or curve of equilibrium, takes up all the permanent load of the structure, without bringing strains on the stiffening trusses. This object was accomplished by erecting the bridge completely before connecting the ends of the straight top chords to the center joint. The rods are provided with turn-buckles, and are so adjusted as to be strained under moving load only.

When the bridge is half loaded the top chords of the trusses on the loaded side will be in compression and the unloaded side in tension. There are lateral and vibration braces between the top chords and also between the chains, proportioned to take up the strains from wind-pressure upon the strains and trusses.

A model of Point bridge was exhibited at Philadelphia and received an award, and Mr. Hemberle was the recipient of quite a number of complimentary letters from most prominent American and foreign engineers approving his new plan.

The total length of the Point bridge is 1,245 feet from back to back of the anchorages, with one middle span 800 feet between center of piers, and one independent trussed side span of 145 feet in length at each shore. The roadway rises from both shores toward the center of the channel with grades not exceeding 3½ feet in 100—the highest point of the roadway being 83 feet above low water. The saddles upon which the chains rest on top of the towers are 180 feet above low water. The deflection of the chain is 83 feet—which is considerably more than usual for suspension bridges—but the stiffening allows of increasing the deflection and thereby reduces the strains in the chains and their weight. The bridge is 34 feet wide from center to center of outside rails and the space is divided into a roadway 21 feet wide and two sidewalks of 6½ feet each by inside iron handrails. The piers up to the roadway and the anchorages are built of masonry. They are founded upon timber platforms sunk to a gravel bed below low water. The masonry is of the best quality—Baden sandstone laid in cement mortar.

The towers are entirely of wrought iron except the bases of the columns. Four columns each 30 inches square braced together by lattice work form the support for each chain, which are carried at the top of the towers on wrought-iron saddles, which are movable on steel rollers to allow for expansion and the elongation of the back chains under strain or from changing temperature.

The chains are formed of link bars, 20 ft. 6 in. long, varying in size from 8 by 2 inches to 8 by 1 inch, connected by pin bolts 6 inches in diameter. There are 12 and 13 bars alternately in the back chains, and 11 and 14 bars in the main chains. Stiffening trusses on top of the chains are 22 feet high in the middle and their upper chord is box-shaped with full rivet splices to resist tension as well as compression.

Outside of the floor are roadway trusses 8 feet high, part above and part below the floor. They are built continuous, in lengths of 100 feet, and are jointed together at their in-ends in such a manner as to allow for expansion and contraction of the iron work. These trusses are suspended from the chains by iron rods placed in pairs every 20 feet and by rigid posts every 100 feet. Iron cross girders, 3 feet in depth, connect these roadway trusses every 20 feet and support two intermediate lines of iron stringers. These stringers and the roadway trusses form the bearers across which are placed the wooden joists for the flooring.

The roadway consists of two courses of 2½ inch oak planks, the lower course being laid diagonal and the upper lengthwise to the bridge. Two street-car tracks are laid upon the floor. The side-walks are laid with narrow 3-inch plank of southern pine. The lateral stiffness of the floor is secured by a double system of tie-rods and the wind pressure is taken up by four horizontal steel wire cables, placed under and connected to the floor.

The specifications for the Point bridge call for a moving load of 1,600 lbs. per lineal foot, to be carried by the structure in addition to its own weight, with a factor of safety of 5, that is, it would require five times the above load to break the bridge down. The 1,900 lbs. per lineal foot is for the 800-feet span, equal to 1,280,000 lbs. which weight is equal to 16 locomotives or equal to the weight of a crowd of 9,000 good-sized people. Such a load is very unlikely ever to come on the middle span of the bridge, and five times that load would not injure the iron work. The back chains on each end of the bridge have a sectional area of 384 square inches, and were all put to actual test of 10 tons per square inch without showing any injury, which will make their reliable supporting power equal to 3,840 tons. For the floor system and the suspenders the proof load is taken at 896 tons for the middle span.

There are 156 suspension-rods carrying the floor, each with a strength of 47 tons, as proved by actual tests which will make their supporting power equal to 7,132 tons, which is equal to the weight of 180 locomotives.

Each of the towers has a sectional area in columns of 504 square inches, and their resistance against failure under the load would be equal to 10,080 tons, whereas the load which ever may come on is only 1,800 tons.

The lateral cables under the floor are at each side, double 2½ inch cast-steel wire ropes, each having an ultimate strength of 210 tons. They would resist the greatest strains brought sideways against the bridge in case of a hurricane, and the bridge has already, under severe winds, proved to be absolutely rigid sideways.

The total cost of the bridge is about $525,000, which is very low compared with other structures of the same magnitude: Cincinnati bridge, being only 200 feet longer, cost $1,800,000. The chain suspension bridge at Pesth, Austria, having a middle span of 666 feet only, cost $2,700,000. St. Louis railway bridge, having spans of 520 feet, cost seven millions.

The president and directors of the Point bridge company deserve great credit for the manner in which they conducted this enterprise. It is due to their efforts and management that this bridge was finished in such short time and at so small cost compared with other bridges in this and other countries.

The American Bridge Company of Chicago, H. A. Rust, president, presented not only the best plan, but also were among the lowest bidders, and the contract was awarded to them for the whole structure complete. The American Bridge Company transferred the contract for the masonry and the foundations to John Megraw, of Allegheny, who has done his share of the work in the most satisfactory manner, and is right in claiming to have the best job of mason work done along our rivers. The award of the contract to an outside company created quite a feeling amongst the Pittsburgers, who are right in claiming their superiority in manufacturing of iron-work, and it may be quite a satisfaction to them that after all most of the work has been done here, with the exception of the forged link-bars in the anchorages and parts of the iron-work, for the manufacture of which the American Bridge Company have special tools in Chicago, all the iron-work was manufactured by Pittsburg parties. Graff, Bennett & Co., furnished the iron in quality unrivaled for the purpose. It is superior in strength and other qualities required for bridge iron to the manufacture of parties making bridge iron their specialty. Mr. Williams, the superintendent of their mill, deserves a great deal of credit for his efforts in obtaining for the unusual large bars a quality of the iron in strict conformity with the specifications.

The manufacture of the iron-work was done at the Pittsburg Locomotive-works, under the supervision of the American Bridge Company's agents. The manufacture of the large link-bars was, after some experimenting, brought to perfection, so as to insure the same strength throughout the entire bar and eyes, which before has been only obtained by the process of Mr. Sellers at Edgemoor.

On July 1, 1875, work was commenced, and by the following winter the masonry was well advanced. Early

in the spring operations were again resumed and continued without interruption to the present date. A great deal of the most difficult work, such as the stiffening-truss, was prosecuted in mid-winter, with the thermometer ranging near zero, and with heavy winds prevailing. Much of the time the material was covered with snow and ice. The rough weather severely taxed the endurance of the men, but in no instance did it get the mastery. Much credit is due Mr. George C. Thorn, superintendent of erection, for the masterly manner in which he conducted the work through such adverse circumstances, and without the occurence of any accident.

The specifications were drawn with considerable minuteness, and required very rigid tests for iron. The links were to be made of the best quality of double refined iron, and in addition to other tests were submitted to a proof strain of ten tons per square inch, sectional area, before they were admitted into the chains. This testing, as well as the inspection of the work, and the giving of levels and distances connected with the bridge, in compliance with the specifications, was intrusted to the resident engineer, who was also the estimating engineer.

The records of the iron test have been carefully preserved, and form a valuable record.

The quantities of the material used in the construction of the bridge are as follows, viz.:

Timber in foundations, 1,442,000 feet, board measure.
Masonry in anchor-walls, 10,868 cubic yards.
Masonry in piers, 7,507 cubic yards.
Iron in foundations, 12 tons.
Wrought-iron in superstructure, 2,084 tons.
Cast-iron in superstructure, 52 tons.
Steel in superstructure, 32 tons.
Timber in superstructure, 810,000 feet, board measure.
Number of links in the chain, 1,832.

As an immediate result of the building of the bridge we should note the approaching completion of the Duquesne Inclined Plane, designed to overcome the gradient of Coalhill, and so situated as to connect with the Point bridge. And yet another, in the proposed street car railway, starting from Fifth avenue and liberty street then along either Penn or Duquesne way to the bridge, across the bridge to Carson street; along the same to Saw-mill run and continued to the Old S one tavern.

The Point Bridge Company are already engaged in constructing a portion of this line connected with the bridge and approaches on their own account.

Also another improvement, diverting travel through new channels, in the shape of a proposed freight and passenger depot for the Panhandle R. R., at the terminus of the bridge.

It is impossible to calculate the benefits to be derived by the different portions of the city in the increased facilities for intercourse afforded by the erection of this bridge. It will undoubtedly restore the old part of Pittsburg about the Point to its former vitality, and will greatly contribute to the speedy development of heretofore almost inaccessible territory on the South Side. By such schemes of internal improvement as this, the thrift and general prosperity of the city is enhanced, and additional comforts to the citizens secured.

And we have no doubt that the parties interested in the construction of the bridge will be amply repaid in this investment.

The bridge will not be open for general traffic before ten days, the approaches not being finished yet. The bridge itself is completed, except the finishing of the hand-rails and the ornamental work of the towers. The ornamental work of the towers will be done quite elaborately and it will greatly add to the beauty of the structure. It is to be of galvanized iron, and the work, already done by Messrs. Stevenson & Cartwright, of Allegheny, awaits only good weather to be put in place. Two more coats of paint are to be put on the bridge as soon as continuous good weather can be expected.

CORRESPONDENCE.

GALVESTON, TEXAS, *April 7, 1877.*

Editor ENGINEERING NEWS:

SIR.—In view of the approaching annual meeting of the American Society of Civil Engineers at New Orleans this month, a few words about Galveston may not be out of place.

Engineering is not flourishing in Texas, although perhaps it is less affected by the hard times here than elsewhere. Many Civil Engineers in this State are out of employment, and more are daily arriving from neighboring States, hoping to find a little relief from the general depression of business prevailing everywhere.

Numerous railroads are being projected throughout the State, but the failure of Congress to aid the Texas & Southern Pacific Railroads has discouraged our capitalists. Galveston, not to be behind other cities, has a three feet guage railroad running some nine miles down the island. It is known as the "Hurly Narrow Gauge." Our city fathers are considering the, by no means easy, problem of how to supply the city with fresh water and water works. Also the completion of a system of sewerage which shall utilize the tide water of the Gulf for flushing and cleansing; the same that was approved by Gen. Beauregard and commenced by Gen. Bragg several years ago. But owing to a heavy municipal debt, and lack of ready funds, it may be some time yet before these problems find a practical solution.

Chas. Morgan, of New York, one of the most enterprising men of the day, and the owner of a large line of steam ships running from this port to New Orleans, New York, Havana; and many other points, has just purchased the controlling interest of the Texas Central R. R. He has already spent nearly a million of dollars dredging a twelve foot channel through Galveston Bay, to connect this line at Clinton, Texas, with his steam ship lines. The work is not nearly completed as yet, but the general government is making surveys preparatory to taking charge of it and making the whole channel, now subject to heavy tolls, open free to all commerce.

The government is now trying a new plan for the improvement of our harbor by means of "Gabions." This very cheap and novel method is due to Capt. C. W. Howell, U. S. A., who first recommended its trial. As you have already given some account of this on p. 267, vol. III. of the NEWS, I postpone comments until further progress has been made. Owing to limited appropriations and the holding back of the greater part of the same last year, but little progress on this work has been made. Recently, however, the balance of last year's appropriation has been made available for the work, and undoubtedly the coming year will go far to prove the success of the experiment. I understand arrangements have been make with the Morgan Line between New Orleans and Galveston, which will enable members visiting New Orleans to also visit Galveston, and return free of charge, so that parties wishing it can have an opportunity, seldom offered, to examine for themselves the merits of a new idea.

In conclusion I would say that a cordial invitation is extended to all members of the society to visit us, and we promise to do what little we can to make their stay among us as pleasant as possible. J. A. HAYWARD.

JACKSONVILLE WATERWORKS—EXTENSION OF TIME.

JACKSONVILLE, FLA., *April 6, 1877.*

Editor ENGINEERING NEWS.

SIR.—Owing to short notice several parties desiring to bid on Water Works requested more time, and there being but few bids in, the Council postponed the matter and have not yet fixed the day of extension.

Yours, etc., T. E. BUCKMAN.

NEW TACOMA, WASH. TER., *March 28, 1877.*

Editor ENGINEERING NEWS:

Permit me to say a word on the pleasure and profit I derive from reading your paper. "May its shadow never grow less." The efforts you have been making towards elevating the professional standard of engineers ought to have the sympathy of every true man; of every one who has an interest in our noble profession. Certainly it ought to encourage us who are younger to labor earnestly in order that we may worthily be counted a member of such a brotherhood. My best wishes for the success of yourself and the child of your care, *i. e.* the ENGINEERING NEWS. Yours truly, D. D. CLARKE.

QUINCY, MASS., *April 5, 1877.*

Editor ENGINEERING NEWS:

SIR.—Business seems to be picking up a little. Most engineers are having considerable work it seems. Pawtucket, R. I., is to introduce the Holly system of water works. Surveys are being made for thirteen miles of railroad, connecting Southbridge on the New York & New England Railroad with Brookfield on the Boston & Albany. The prospect is very good for a narrow gauge railroad in Vermont, from Brattleborough to Whitehall. Brookline, Mass., has voted to build a large trunk sewer this summer. It will empty into Charles River at present, but connect with the Boston system at some future time. Wm. S. Barboun is re-elected City Engineer of Cambridge. Architecture is better now than it has been for some time. Yours truly, C. H.

WAUKEGAN, LAKE CO., ILL., *April 7, 1877.*

Editor ENGINEERING NEWS:

SIR.—Enclosed find amount of subscription for ENGINEERING NEWS. Old as I am, I find in each number something that to me is new. In my opinion it would pay every township in the State to subscribe for ENGINEERING NEWS for the use of Highway Commissioners. Probably there is not one in ten of the Road Commissioners in the State that ever dream there is the least science in making embankments. A pile of dirt—nothing more—no matter how placed. Enough study to make them distrust their own knowledge would induce the taking of counsel, and would save much to the tax payers. Then the permanency of culverts, or their abutments, would frequently be improved, if the road authorities knew the necessities of using good cement instead of common lime mortar, By the way, would it not be well for you, if you have the leisure time to write up the question of building common roads. You might not make much money by it, but the public would indirectly be benefitted by the knowledge that some would thereby gain by coming in contact with your many not always stupid readers. Your journal is an educator of not only professional men, but of all classes who read it, or converse with those who do. I cannot hope that you will receive all the patronage you deserve, but I do hope that you will get sufficient patronage to induce you to continue its publication. Long life to ENGINEERING NEWS. Yours truly,

H. W., *County Surveyor.*

OBSERVATIONS UPON SEWERS AND FORMULÆ.

PROVIDENCE, R. I., *April 7, 1877.*

Editor ENGINEERING NEWS:

SIR.—Assume, which is practically correct, that a sewer 66" circular, is flowing one foot deep in water, the length of arc then will be 4.847 feet area = 2.9515, the H M R = .60958, and the grade 1 in 1000. Neville makes the velocity = 3.46 − .93 = 2.53 per second; and Molesworth gives 1.860; Eytelwein 2.3466, very near Neville. It commences to rain heavily, and the sewer is filled to within 18" of the crown, then the area of water = 18.50 sq. feet, and V = 4.38 Neville; Molesworth 2.6; and Eytelein 3.86. So there is considerable difference between the three, but Neville gets very near what I should think the actual result. The area of the water will then 18.50, wetted perimeter 11.234, and H M R 1.647, making the discharge 4866.2 cubic feet per minute. Now there are running into this sewer seven 20", ten 22", one 12", and according to the formlæ, $D = \left\{ \frac{m^2}{1450\,S} \right\}^{\frac{1}{6}}$ the 20" sewer will drain 16 acres with a grade of 1 in 500 which is very near their grade; also the 22" will drain each 22 acres, and the 12" pipe 10 acres, making a total of 166 acres.—this is allowing for one inch to be raining per hour and half getting into the sewer, and the amount of water flowing would be $166 \times 30\frac{1}{4} = 5021$ feet which is very near the amount given by Neville as above, and taking the whole sewer running full the discharge would be 7227.8 cubic feet per minute, or 239 acres, condition as stated. But Roe says in his tables that a 60" sewer level will drain 570 acres—over twice as much, and I cannot understand how this is, nor yet how Mr. Ryall, in Jan, No. 13, can put Roe into a formulæ; for if you plat the table, you get an irregular curve, $D = \left\{ \frac{m^2}{S\ 1450} \right\}^{\frac{1}{6}}$ gives 40 acres nearly, as the amount this sewer will drain, against 239 acres which would be got by Neville, and one supposed to by Bazalgette gets $\frac{3 \log A + \log N + 6.8}{10} = D$ in inches, giving in this case 629 acres, something like Roe's tables. Now all the formulæ I have seen have to have a grade or the quantities become infinite. Now if we take

$$D = \left\{ \frac{m^2}{1450\,S} \right\}^{\frac{1}{5}}$$

we get 171 acres, and why such a change should be made to the extent given by Mr. Clark, of Boston, in the same No. of Jan. 13, that the house connections and gullies give a greater velocity to the water, when my experience is the other way. Baldwin Latham says he has known sewers surcharged by lateral drains having a steeper grade, and I can quote lots of these cases, and in answer to Mr. L. L. Nichols, March 24th, I should say that $D = \left\{ \frac{m^2}{1450\,S} \right\}^{\frac{2}{5}}$ is the nearest the truth.

W. W.

FULTON, MO., *April 5, 1877.*

Editor ENGINEERING NEWS:

SIR.—Will any length of time legalize corners illegally established by a County Surveyor (that is, contrary to the instructions from the Commissioner of the General Land Office, and the Statutes of the State), and justify his successor in office in adopting such corners as correct, when he knows them to be wrong, and divide up sections from said corners? Would like to know your opinion, and that of some of your correspondents, at the earliest possible time. COUNTY SURVEYOR.

Acquiesence for a long time (*e. g.* for 18 years) even in erroneous location, is conclusive on the party making or acquiescing in such location. Rockwell *v.* Adams, 6 Wend, (N. Y.) 469.

Where a boundary is disputed between parties who own adjoining tracts, and the parties employ a surveyor, who runs out the line, and marks it in a plat in their presence, as a boundary, after *20 years* corresponding possession, they are concluded by it. Boyd *v.* Graves, 4 Wheat. 53.

Fifteen years acquiesence in an imaginary divisional line between adjacent proprietors establishes that line as a boundary. Beecher *v.* Parmele, 9 Vermont, 352.

A division line which has been agreed upon for *thirty* years, cannot be altered. Chew *v.* Morton, 10 Watts. (Pa.) 321.

The *original* surveys by which the government sold its land and conveyed it to the purchaser, establish the right of the parties as to the boundaries. No line which will vary the rights thus acquired, can afterwards be established, *without consent* of all parties. May *v.* Buskins 12 S. & M. (Miss.) 428.

So, in trespass against the defendant for removing the plaintiff's fence, proof that by the Government Surveys the fence was on defendant's land cannot be affected by proof of other surveys, not conforming to the Government Surveys. *Ibid.*

The simplest and most easily comprehended system of subdividing large tracts of land is the Rectangular; the rules for relocation of missing corners are very distinct, and it is only through gross carelessness or ignorance that errors in surveys are allowed to be fastened on a neighborhood to entail endless and vexatious litigation. The opinions which we have recited above show that a long period of acquiescence in an erroneous survey fixes the boundary line laid down by such; it does not, however, affect adjoining sections, or as we understand it, the sub-division of the section in which said erroneous boundary is. In our own practice we always have held to one principle—*to stick by the government,*—and in the establishment of disputed boundaries we try to get as nearly on the identical track over which the Government Deputy's chain was dragged as we possibly can. His route is mapped out by the Government who has also put down in plain figures the distances between his half-

mile and mile halting places, and by innumerable decisions from its highest officer has established the method of comparing the measurements of succeeding surveyors and those of the Deputy. We hold then that mutual consent between adjacent proprietors may establish a line between *their* lands; their action does not affect the boundary line of other portions of the same section, and in making surveys thereof we would simply ignore all such agreed-upon lines, determine by measurement or evidence the location of original monuments as nearly as possible, and pay no attention to the mistakes of a former surveyor. Get as near to the court of last resort as possible,—and that is the Government.—[Ed.

NOTES ON THE FORMULÆ FOR STRENGTH OF COLUMNS.

COLUMBUS, OHIO, *April 5, 1877.*

Editor Engineering News:

Sir—The difference between Hodgkinson's and Gordon's and Rankine's formulæ seems to have given rise to an error which has become so wide-spread among the profession as to require some notice.

Hodgkinson obtained from his experiments on iron columns the following formulæ for solid columns of cast iron:

$$W = \frac{d\ 3.6}{L\ 1.7} \times 44.16 \text{ for square ends.}$$

$$W = \frac{d\ 3.6}{L\ 1.7} \times 13.0 \text{ for rounded ends.}$$

Subsequently he modified these formulæ as follows:

$$W = \frac{d\ 3.5}{L\ 1.63} \times 42.3 \text{ for square ends.}$$

$$W = \frac{d\ 3.76}{L\ 1.76} \times 14.9 \text{ for rounded ends.}$$

In all of which W = breaking load in tons.
d = diameter in *inches.*
L = length in *feet.*

Gordon's formulæ, derived from the same experiments, are:

$$W = \frac{f\ s}{1 + a\frac{l^2}{h^2}} \text{ for square ends.}$$

$$W = \frac{f\ s}{1 + 4a\frac{l^2}{h^2}} \text{ for rounded ends.}$$

These formulæ were subsequently modified by Prof. Rankine as follows:

$$W = \frac{f\ s}{1 + a'\frac{l^2}{r^2}} \text{ for square ends.}$$

$$W = \frac{f\ s}{1 + a'\frac{l^2}{r^2}} \text{ for rounded ends.}$$

In both Gordon's and Rankine's formulæ
W = breaking load in *lbs.*
f = modulus of resistance to crushing.
s = area of section.
a and a = co-efficients depending on the material.
l = length in inches.
h = least dimension of cross section.
r = least radius of gyration of section.

The error to which we have alluded is this: Hodgkinson's rule makes the strength of rounded ends *about one-third* that of square ends; and this ratio seems to have become so firmly impressed on the minds of the profession that they cannot get free from it; and while most engineers have discarded Hodgkinson's formulæ in favor of the others, yet this ratio *one-third* is frequently applied while using Gordon's or Rankine's formulæ for square ends.

If we transpose Gordon's formula for square ends, so as to get the area (s) in the left hand member, it becomes

$$s = \frac{P}{f} + \frac{P}{f}\ a.\ \frac{l^2}{h^2}$$

which, being interpreted, means that the area of the cross-section must consist,

First. Of a portion $\frac{P}{f}$ to resist *crushing*, and which is entirely independent of the *form* of section, and length of column, and which for a given load is constant for all ratios of length to diameter.

Second. Of an additional portion to resist *bending*, and which depends on the form of section and ratio of length to diameter.

The resistance to bending, as between round ends and square ends is analogous to the difference, in the resistance of a *beam* with fixed ends, and with ends resting on supports; hence the use of the factor 4 in Gordon's and Rankine's formulæ, as applied to round ends. But this factor applies only to that additional area required to resist bending, and not to the area which resists crushing.

The ratio of strength of square end and round end columns, is therefore a variable quantity; the difference increasing as the ratio of length to diameter increases, and diminishing as this length-*ratio* decreases. By Gordon's rule the ratio is greater than 75.

Thos. H. Johnson, C. E.

The success of the steam street cars in Philadelphia seems to be assured. During a single week the receipts of five horse-cars averaged $65, while those of five dummies averaged $100. The average expense of a horse-car during that period was $62 86; that of a dummy $54 80.

ON THE PROBABLE ERRORS OF LEVELING; WITH RULES FOR THE TREATMENT OF ACCUMULATED ERRORS.*

BY WILFRED AIRY, B. A., M. INST. C. E.

(*Continued from page 84.*)

Table VI.—Instruments and Staves used in Initial Leveling.[1]

Instrument	Great Britain.	India.	Switzerland.	France.
Spirit level..... Seconds of arc in tilt of telescope corresponding to 1-inch of the bubble run of the bubble.....	5"	3½"	3"	3" to 7"
Telescope..... Focal Length..... Object Glass.	24 ins.	21 ins.	16 ins.	19 ins.
Diameter of Object Glass.	2⅝ "	2 "	1¼ "	1¼ "
Magnifying power.....	50	42	42	36
Staves..... Length.....	10 ft.	16 ft.	9.84 ft.	6.100 ft.
Graduated to.....	1-100 ft.	1-100 ft.	3-100 "	3-1000 "
Read to.....	1-1000 "	1-1000 "	3-1000 "	3-1000 "
Maximum distance of staves from Instrument.....	5 chs.	10 chs.	5 chs.	6½ chs.

[1] The metrical values of the foreign measures have been reduced to English units for the sake of comparison.

By due attention to all the ascertained causes of error a high degree of accuracy may be secured, and this Paper cannot better close than with a reference to the astonishing results obtained in India under the able management of Colonel Walker. From the Report on the Spirit Leveling Operations in India dated 1866 the following information is extracted:—

Section.	Length.	Maximum Divergence of two observers.	Terminal Divergence.
	Miles.	foot.	foot.
Calcutta to Tilliagarhi....	242	.20	.15
Tilliagarhi to Patka Gerouli.....	346	.40	.38
Agra to Patka Gerouli ...	342½	.15	.05

Sir. G. B. Airy, Astronomer Royal, observed that, although he had run a few miles of level himself, he could not make any practical notes upon this communication; but he would say one thing, that, referring to the state of knowledge upon the matter as it was some years ago, something of this accurate character was much wanted. On one occasion he wished to know how far reliance could be placed upon the levels between Manchester and Runcorn, and applied to an engineering friend, who did not profess to be able to answer the question accurately, but referred to three others who were considered likely to be perfectly informed upon the matter; and one of these gentleman said he thought the levels might be trusted to 6 inches, another put it at 2 inches, and the third at 1 inch. That was the state of things some years ago. No doubt they had grown better now; but still he was pleased to hear that there was an attempt at getting greater accuracy on this point, and by a collection of the best measures. Amongst those that had been brought together was that of Switzerland, with which, although less extensive than those of Great Britain and India, extraordinary pains had been taken. He had the good fortune to be personally acquainted with M. Plantamour, who was at the head of that, as well as with the officers at the head of the two other surveys, and he was quite sure that, in Switzerland, everything was done which could be done by men careful and well acquainted with the mathematics on the subject. As far as he could remark, there was but slight mention in the Paper of one of the discoverable errors, namely, that constant error which produced a difference in the apparent levels according as a line was leveled in one direction or in the opposite direction. This had excited attention a number of years ago on the occasion of leveling from the English Channel to the Bristol Channel. Amongst other causes assigned, he did not know whether there had been an allusion to the possibility of an error from the possible circumstance—for he was not sure that it was a real one—of always reading the front staff before the back staff, or the contrary; it was conceivable that that should cause such an error. With regard to the mathemathies of the case, as applying to a geodetic survey, he was glad they were brought into shape, and he would point out the nature of the mathematics concerned. Supposing that leveling was effected in a triangle between these stations; it was to be expected in all cases that there would be some degree of inconsistency; but by proper treatment, understood by practical men, the determination of the most probable errors amongst them could be laid down, and the way in which the inconsistency should be divided between the three stations. In another triangle, or a trapezium or polygon, the same could be done there; but suppose those were connected by other levels which joined one of the figures to the other figure, the problem was immediately changed. Neither of those could be treated separately if they were joined by leveling from the stations of one to the stations of the other. The problem came within the case which in a little book that he had written upon the subject, he had called 'entangled errors,' and admitted of accurate treatment leading to a definite result in every case. The best thing, therefore, that he could do was to recommend engineers to read his book.

Mr. Longridge said, although the Paper might not be of much general use to Civil Engineers, it was still one which in the higher operations of leveling, so necessary for other purposes, must be of great value. In their operations engineers did not require that extreme accuracy which called for the treatment of the subject in the way in which it had been dealt with by the Author. If the system of leveling was carried on with tolerable care, and properly checked, they would arrive at results which were quite as accurate as was required for such purposes as waterworks, canals, and railways. He was surprised that any engineer could have told the Astronomer Royal that between Manchester and Runcorn there might be as much difference in the estimated level as 6 inches; for in the days of the Liverpool and Manchester railway, when the instruments used were not like those of the present day, but something more like a mason's level, he did not believe engineers got further wrong than 6 inches. In his own early days, when leveling the North Midland railway, the system adopted was that the levels were checked by another person. If a difference was found of 2 inches in a distance of 30 miles, the work had to be done over again, and he could safely say in a distance of 30 or 40 miles, if the levels did not check within that limit, the work was thought very bad indeed. If the ground was rough, there might be loss in going up hill; but the gain would be as much in going down, although it was quite true there might be an error at the top of the hill. Another error spoken of was that arising from the staff not being held vertically. Formerly the staves were made with levels and plum-bobs in them. That, however, was perfectly unnecessary, and the only thing required was to instruct the staff-holder, when he held up the staff, instead of keeping it perfectly vertical, to move it backwards and forwards. The lowest level could then be read off. Another cause of error was from shifting the staff. To obviate that, he had small tripods, which the staff-holder pressed with his heel into the ground and held the staff on, so that the staff was not shifted, but was simply turned round. No doubt all these details were well known to practical men. Referring to leveling instruments, he wished to mention one he had used with great advantage for some years, particularly in rough ground. It was, he believed, devised by Mr. Metford, and was made by Pastorelli. It differed from the ordinary level in not having parallel plates, but instead a ball and socket and three screws. The level had a circular bubble as well as an ordinary bubble, and it was set by using the ball and socket. Directing it upon the staff it could be set almost exactly right, the bubble being adjusted by the slightest pinch upon the screw. It was done in a moment, instead of having the four screws to adjust, which was tedious on rough and sidelong ground. He believed a third of the time might be saved on rough ground by using such an instrument; and he therefore recommended it to those who wished to get through their work quickly.

Mr. Barlow, Vice-President, thought Mr. Longridge had hardly caught the sense of the Paper. There were sources of error, if he understood the Author, which could not be got over by checking by any person, arising, for example, from leveling from point A to B as compared with leveling from B to A. The Astronomer Royal had mentioned the levels taken from the British Channel to the English Channel—from Portishead to Axmouth—a distance of 74 miles. The instruments used were of the most perfect class, and the levels were done with every possible pains that could be taken for such work. The levels were taken for a Committee of the British Association, under the immediate direction of Professor Whewell, and in that case an error had been made at the end, comparing the levels taken from north to south with those taken from south to north, exceeding 1 foot. Starting from the northern end in a distance of 12 miles, there was an error of 35-100 foot; in 27 miles, 57-100 foot; at 43 miles, 75-100 foot; and in the whole 74 miles, 1 3-100 foot. The gradual manner in which that error occurred from one end to the other showed there was something beyond that which ordinary levels professed to check.

To be continued.

* From the Proceedings of the Institution of Civil Engineers, London.

THE STRENGTH OF COLUMNS.

The letter of our correspondent, on page 92 of our last issue, has called the attention of our readers to the formulæ for the strength of iron columns as commonly used, and, both for the sake of more strongly insisting on some of the points there brought out, as well as to present the formulæ in a little better shape than that in which the printer there set them forth, we have thought best to devote a little more space to the matter.

The formulæ of Mr. Eaton Hodgkinson, as published by him in 1840, in the *Philosophical Transactions*, and in 1846, in *Experimental Researches on the strength and other properties of Cast Iron*, were practically of the form

$$\text{Breaking load} = A\,\frac{hm}{L^n},$$

in which the breaking load is given in tons, h is the diameter in inches, L the length in feet, and A a constant multiplier in tons. The exponent m is sometimes given, for cast iron, as 3.6, sometimes as 3.5, and sometimes as 3.55, while n also varies from 1.7 to 1.63, these number supplying to square ended, solid cylindrical columns. This difference in the exponent is not very material. The multiplier A varies with the quality of the iron, and is often taken as 44.16 tons. Similar formulæ were given for wrought iron, the constant A being materially different and the exponent l being 2. Liberal quotations from Hodgkinson may be found in the thirteenth chapter of Stoney on the Theory of Strains, and Wood's Resistance of Materials, p. 56, shows how exponents may be deduced from experiment. That a column with both ends free to turn or bend sideways is much weaker than one whose ends are fixed in direction is manifest, if we consider that one with fixed ends must develop upon flexure under a longitudinal force, two points of contraflexure, making the portions between these two points, which alone may be compared with a pillar free to turn on its ends, only half the length of the original column.

But without citing in detail the modification of symbols, in the formulæ written above, as any engineer has access in his books to the quantities referred to, it is proper to call the reader's attention to the fact that Hodgkinson expressly limits his formulæ to cast iron columns when the ends are flat and firmly bedded, whose lengths are more than *thirty* times their diameter, and to wrought iron columns whose lengths exceed the diameter *sixty* times; or, if both ends are rounded, to one half these lengths. For cast-iron columns of medium length, that is, less than thirty diameters, he modifies as follows:— If b denotes the breaking load of the pillar by the above formula, and c the crushing load of a short block of the same sectional area then the

$$\text{Actual breaking load} = \frac{4bc}{4b+3c};$$

which later formula will modify results from the preceding one very materially.

Mr. Lewis Gordon derived a formula from Hodgkinson's experiment which, as given by Prof. Rankine, is, if P denote the crushing load of a long pillar, in pounds, S the sectional area of material in it, and square inches, l its length and h its least external diameter in the same units of measure

$$P = \frac{fS}{1 + a\frac{l^2}{h^2}}.$$

The constant f is understood to be the resistance of the material to crushing, and is given as, for cast iron cylindrical columns 80,000 lbs. per sq. inch, and, for wrought iron regular columns, 36,000 lbs. per sq. inch It is often customary in America to make f for wrought iron cylinders considerably larger, 45,000 lbs. to 50,000 lbs.; a few experiments on hollow columns have confirmed this latter value. If the columns are fixed at both ends, for cast iron $a = \frac{1}{800}$, and for wrought iron $a = \frac{1}{3000}$; if rounded or jointed at both ends use $4a$ in place of a; and, if one end is fixed and the other jointed, Rankine gives in his *Machinery and Mill Work* $\frac{16}{9}a$ in place of a.

Gordon's formula is in general use, and with satisfactory results so far as the sections are concerned for which it was devised. It is not very handy but is the best we have. What our correspondent remarks about the division of the cross-section into a portion to resist crushing and a portion to resist bending is well stated. That a formula of such a shape might be expected to apply may be concisely shown in the following manner:—The *effect* of a load on a pillar may be divided into two parts, first, a direct thrust giving a uniform compression on the fibres $= p' = \frac{P}{S}$; second a bending moment causing the pillar to yield in the direction of its least dimension, h. This decomposition is that of a force at a distance from an axis into a force and a couple at the axis. This bending moment, at the point of maximum deflection of the column from a straight line, may be represented by the expression Pv, where v corresponds with the deflection of a beam under a transverse load. Let the stress on the external fibres due to this bending be p''. Then since the moment of resistance of the column to flexure may be put $np'' = bh^2 = M$, where b and h are the two external dimensions of the cross-section, n a numerical factor depending on the shape of the cross-section, and M = bending moment. We have therefore

$$p'' = \frac{M}{nbh^2} = \frac{Pv}{nbh^2} \therefore p'' \text{ varies as } \frac{Pv}{bh^2}$$

But the greatest safe deflection v varies as $\frac{l^2}{h}$, therefore,

$$p'' \text{ varies as } \frac{Pl^2}{bh^2}, \text{ or as } \frac{Pl^2}{Sh^2}, \text{ or as } p'\frac{l^2}{h^2}$$

hence the total stress on the most strained fibre

$$f = p' + p'' = \frac{P}{S}\left(1 + a\frac{l^2}{h^2}\right) \text{ or } P = \frac{fS}{1 + a\frac{l^2}{h^2}}$$

where a = constant to be found experimentally.

As wrought iron columns are of various sections a formula was desired which would apply to other forms than rectangles. The value of p' in the above demonstration would be unchanged as long so S was constant, no matter what the form of cross-section; but p'', depending on the deflection, would naturally change with the *moment of inertia*, a quantity entering into all calculations of beams. As the moment of inertia may be written = the cross-section multiplied by the square of the radius of gyration—Prof. Rankine sought to introduce this quantity, denoted by r^2, in place of h^2 in Gordon's formula, which would then apply to any section of column. The formulæ as so modified are not understood to be exact, but to be the best we have until experiments are made to supply new and better data. The moment of inertia of a rectangle of height h and breadth b, above an axis parallel to b, passing through its centre of gravity, is $\frac{1}{12}bh^3$. Then, dividing by $S = bh$, we get $r^2 = \frac{1}{12}h^2$ or $h^2 = 12r^2$. Since the original formula applied to a wrought iron strut or column of rectangular cross-section, we may write $12r^2$ for h^2 without error, and we thus give Prof. Rankine's form

$$P = \frac{36000\,S}{1 + \frac{l^2}{36000r^2}}$$

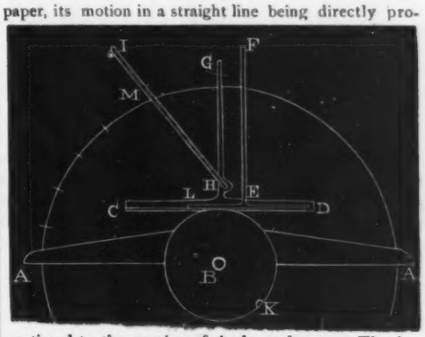
Any other form of cross-section will then be assumed to vary as to strength according to r^2, For **L**, **T**, and **H** sections the original formula is sometimes used with good results when $1\frac{1}{4}l$ is substituted for l.

That some better rules for proportioning columns are needed is very apparent. Prof. Vose gives, in his *"Manual for R. R. Engineers,"* page 143, some of the results for cast iron columns obtained by using the formulæ found in various text and hand-books; the discrepancies are very large. We had hoped that the U. S. Commission for Tests of Iron and Steel would furnish such data as are needed for the establishment of formulæ adapted to American metal and the sections, rolled or built, which are in use; but the failure of Congress to make the much needed appropriation cuts us off, at least for the present, from this source of information. Experiments on full-sized columns, both as to length and section, are requisite, and they are too costly for a private purse. Mr. Chas. Macdonald, in closing his analysis of the Ashtabula Bridge, before the American Society of Civil Engineers, after attempting to arrive at some conclusion as to what the braces (6 inch rolled I beams) ought to carry, remarks, "a careful study of the behavior of the compression members of this bridge must impress us with the necessity of more perfect experimental knowledge of the strength of iron in the form of struts. Almost the only information we now have is crystallized in that somewhat flexible expression known as Gordon's formula, and we have seen how difficult it has been to extract any comfort from it on this occasion."

We have said nothing about the importance of firm, square bearings on the ends of columns, and of the resultant of the pressure lying along the axis of the strut, both very important points. We have only attempted to call attention to the different formulæ, how they are derived, and to the difference between square ended and round ended columns. No ratio of three to one properly expresses their comparative strength In conclusion we would commend, to such of our readers as may have access to the comparatively little known book of Baker's, *"On the Strengths of Beams, Columns and Arches,"* published by Spon, that portion on the Strength of Columns.

CIRCLE DIVIDING INSTRUMENTS.

The device illustrated in the accompanying sketch has been recently invented for dividing a circular arc or an entire circle into any number of equal parts. It consists of a straight edge A A to which is attached a circular disc B; to the same center on which this disc B turns is fastened an arm G H, with a cross head C D in which slides a bar D L carrying at right angles the arm E F. A flat steel wire, fastened at D to the bar, passes round the circumference of the disc and is attached to it at K; other wires fastened at the extremity L pass to K around the other portion of the disc. It is evident then that, as the disc B is turned by the straight edge A, the arm E F will travel parallel to itself across the paper, its motion in a straight line being directly proportional to the motion of A along the arc. The bar H I is hinged on a pin at the end H and has a number of equidistant holes drilled along its length. All of the other parts are sufficiently raised from the paper to permit A A to revolve below them.



To divide a circle proceed as follows:—Place the center B over the center of the circle and retain it there by a pin through the hole at B. If it is desired to begin the division at a definite point, swing A round to the desired point, insert a pin in the hole at the center of motion of the bar H I, and move the arm G H until the pin comes in contact with the edge of E F. Then fasten the extremity G to the drawing board by a projecting point at that end; remove the pin from H and insert it that number of hole, say at M, which corresponds to the desired number of divisions in a semi-circumference or a circumference; swing A A through exactly 180°, causing E F to move toward I, and bringing the other end of A to the point first determined upon. Then move the end I of the bar H I until the pin in its hole at M will bear against the side of E F in its new position. Fasten I in its new location by a pin. The instrument is now set, and it is apparent that a movement of A through 180° will cause E F to move from M to H; hence a shifting of the pin at M to the successive holes in the bar will cause A, when E F is moved, to touch the pin, to pass over the required spaces of arc. For an odd number of divisions of a circle the number of holes may be doubled, and the pin moved over two at a time.

The instrument will also divide any angle in any number of parts. It is expected to be especially useful for laying out teeth of wheels. A patent has been applied for.

In his report to the Common Council, of Chicago, concerning the "Crib," Gen. W. Sooy Smith declares that structure to be in good and safe condition, and he

sees no reason why it will not continue so for many years to come. He states, however, that a protection wall on the side most exposed to the northeast storms would render it still more secure.

THE number for March, 1877, of the "Transactions of the American Society of Civil Engineers" contains three papers of interest; a short one on "A Water Conduit under Pressure," by John F. Fanning; a report by Chas. Macdonald on the "Failure of the Ashtabula Bridge," which is in harmony with the views already expressed in our pages; and a paper on "Co-ordinate Surveying," by Henry F. Walding. All the communications are illustrated. With this number is bound the report of the Chief Engineer, W. A. Roebling, of the New York and Brooklyn Bridge, covering the years 1875 and 1876, with the reports of his assistants. Engineers will find much matter of interest in this latter pamphlet of more than 100 pages.

ON another page we give the table of Contents of Dr. Weyrauch's treatise on the "Strength and Determination of the Dimensions of Structures of Iron and Steel," a little book which is presented to the Engineering profession at a most opportune time. Since the accident at Ashtabula, public attention has been largely drawn to the subject of iron bridge construction, and everything relating thereto is of peculiar interest. This interest is also increasing and it has been found expedient by the managers of our leading railways to investigate the condition of the bridges on their several lines of road. The specialty of bridge engineering may be considered as rising rapidly in importance and to those of our readers who are ambitious of preferment in this branch of their profession we can confidently recommend the treatise of Dr. Weyrauch as almost indispensable in studying the subjects of which it treats. That three such names as Weyrauch, Du Bois and Thurston should be associated in the preparation of a work on this subject is a very sufficient guarantee of its worth, while in the excellence of its mechanical execution together with the low price at which the work is placed upon the market, everything has been done to ensure its extensive distribution among the engineering profession.

Quite a large delegation will go from Chicago to attend the Convention of the American Society of Civil Engineers in New Orleans.

The Secretary of the Civil Engineers' Club of the Northwest has furnished certificates to the following named persons, most of whom will leave Chicago Monday morning via the Illinois Central Railroad:

From Chicago.—E. S. Chesbrough, Mrs. Chesbrough, S. S. Greeley, E. Hemberle, W. H. Lotz, Richard Potts, C. W. Durham, L. P. Morehouse, Mrs. Morehouse, Geo. H. Frost, Miss. Hunt, R. J. McClure, W. F. Goodhue, G. C. Morgan, E. Powell, F. W. Clarke, J. E. Thomes, J. R. Willett. L. E. Cooley, Evanston, Ill.; Col. F. U. Farquhar, U. S. A., Mrs. Farquhar; W. L. Baker, Detroit, Mich.; H. P. Devock, Detroit, Mich.; J. L. Gillespie, St. Paul, Minn.; Max Hjortsberg, Chicago; M. Lane, Milwaukee, Wis.; Ch. MacRitchie, Milwaukee; Capt. O. E. Michælis, U. S. A., Mrs. Michælis; Alf. Noble, Detroit; W. S. Pope, Detroit; J. E. Sewell, St. Paul; J. R. Straughan, Ft. Wayne, Ind.; T. J. Nicholl, Springfield, Ill.; Mrs. Nicholl; R. P. Morgan, Jr., Springfield; Gen. W. S. Smith, Maywood, Ill.; Prof. E. N. R. Talcott, Morgan Park, Ill.; D. W. Wellman, St. Paul; J. F. Olney, Buffalo, N. Y.; W. H. Searles, Rochester, N. Y.; H. Seymour, Jr., Utica, N. Y.; C. H. Strong, Cleveland, Ohio; Mrs. E. P. Mason, Ann Arbor, Mich.; Miss. Mason, Ann Arbor, Mich.; R. Moore, St. Louis, Mo.; L. S. Olmstead, Jacksonville; L. M. Johnson, Keokuk, Ill.; B. F. Morse, Cleveland, Ohio.

REPORT ON THE KANSAS CITY WATER-WORKS.

Nos. 10 and 11, Vol. III, of the NEWS, for March 4 and 11, 1876, contain some account, with illustrations, of the Kansas City Water Works. We have therefore thought that the report on their condition, recently made by Col. Henry Flad and Thos. J. Whitman, of St. Louis, would prove interesting to our readers, and perhaps instructive. The engine-house, receiving cribs, settling basins, pump well and section of upper reservoir embankment, referred to in the following report, will be found in the drawings in the numbers of Vol. III above mentioned.

A pamphlet of the Holly Manufacturing Co. puts the daily capacity of the Kansas city works at 5,000,000 gallons; the length of pipe about 16 miles, all iron, 4 in. to 20 inches; in operation since Feb. 1875. fo supply about 40,000 people; duty of engine, with western coal, 50,000,000 lbs. raised 1 foot with 100 lbs. of coal; with anthracite or Pittsburgh coal, about 60,000,000; same class of engines have given on a close test 74,000,000 ft. lbs.; consumption of coal about 3 tons per day; highest elevation of hydrant above engines 230 ft., elevation of engines added, equal 264 ft. lift, and distance of same about 3 miles.

The report is as follows:—

ST. LOUIS, MO., *Dec. 23d, 1876.*

Hon. Turner A. Gill, Mayor Kansas City Mo.:

SIR.—Our examinations of the Water Works at Kansas City have been conducted with a view to enable us to form an opinion as to whether the works built by the "National Water Works Company" comply with certain conditions of the contract, and also as to the approximate cost and value of the works.

We divide the subject under five heads as follows:

1st. Does the quality of the water furnished comply with the requirements of the contract?

2d. Do the quality of materials furnished and the workmanship performed fulfill the demands of the contract?

3d. Can the tests called for by Sec. 8 of the contract be successfully performed by the works as now constructed?

4th. Approximate estimate of the cost and value of the works as now built?

5th. Estimate of the value of such parts of the work as in our opinion may be made available by the city.

The contract Sec. 1, provides that the "National Water Works Company, of New York," is authorized under certain conditions to "take, purify, store, conduct and distribute on and throughout the said City of Kansas, pure, well settled and wholesome water," and Sec. 14 the Company agrees and binds itself at "all times" to furnish a full and sufficient supply of "good, pure, well settled and healthful water * * * * such water to be suitable for domestic purposes."

The chemical analysis given in the report, purporting to be an analysis of the water from the Kansas river, and upon the result of which the location of the works seems to have been determined, is not, in our opinion, conclusive evidence as to the quality of the water furnished by these works.

In the first place there is no certainty that the water analyzed by Dr. Fay (see page 35 of report) was taken from the Kansas river. Dr. Fay has distinctly stated to us that he had no knowledge as to where the water was procured, that from his previous examination of the water purporting to come from the Kansas river he was exceedingly dubious in regard to these samples coming from the same source, and further, that the questions which were answered in his report dated May 16th, 1864, appear to him to have been framed rather for the purpose of getting favorable answers, than for the purpose of ascertaining all the facts in regard to the quality of the water.

In the examinations made by Whitman in 1872-73 for supplying water to Kansas City, the same Chemist (Dr. Fay) made the analysis and reported against the water taken from the Kansas river as being inferior to the water taken from the Missouri at Wyandotte.

As was stated in the report made in 1873, the samples of water analyzed by Dr. Fay (see page 34 of the report) were taken at a time when the water of the Kansas river was affected by back water from the Missouri, therefore the water of the Kansas river is probably even less fit for a city's supply than was indicated by these specimens.

And again, from other statements made to us by Dr. F., we consider it very doubtful whether the table on page 36 of the report refers to the water of the Kansas river, but rather believe that it is a comparison of the water of the Missouri river, taken at Kansas City with water taken from other sources.

From the best information we can procure on the subject we do not consider that the Water Company in taking water from the Kansas river have complied with the terms of their contract as regards the subject of quality, yet it would be necessary to have more positive evidence on this point, and we would therefore suggest to you that the best method to ascertain the facts of the case would be to have samples taken from the Kansas and Missouri rivers at least once a month, for a series of months and have a thorough analysis made of them by a competent and reliable chemist. In this way testimony could be procured on this point that would either confirm or set at rest the very prevalent belief that the water of the Kansas river is not fit for the supply of your city.

As to the character of the work done, it is our opinion that neither the spirit nor letter of the contract has been complied with in the quality of the materials and workmanship and in certain parts of its construction.

Sec. 4 of the contract (page 10 of the report) states that "if, upon examination, it be found that such works are not in all respects in good condition, and of first-class and sound materials then the city shall not be required to purchase the same at any time nor at any price;" also Sec. 17 of contract (page 20 of report) states "the said Water Works Company agree that their machinery and works shall be of the most durable material and first-class in all respects."

Our investigations lead us to the opinion that the "receiving cribs" at the river, the "receiving well," the "lower reservoir" or settling basin and the "upper" or distributing "reservoir" are temporary structures, that they do not fulfill the conditions of the contract, and are not, in any sense, to be considered permanent and reliable work.

The "receiving cribs" are constructed of pine timber and liable to decay in a short time. This timber work is exposed to the alternate action of air and water and under such circumstances cannot be expected to last long. The construction of the cribs as built would indicate that they were expected to answer the purpose for which they were designed but a short time.

The "receiving well," from the description given us, and as stated in the report, was made by sinking a wrought iron caisson, fourteen feet in diameter and eighteen feet high, until its lower edge was thirty-nine feet below the engine-room floor. After the wrought iron cylinder was brought to place, the earth was excavated one foot below it at the sides, and three feet in the centre and then the entire bottom covered with two and a half feet of concrete; after this, the earth outside at the top was excavated to a depth of about three feet and the space filled with concrete and masonry, and upon this masonry the engine foundations are built. This construction leaves about fourteen feet of the well protected from caving, only by the wrought iron cylinders; as soon as the iron rusts through, which must occur in a few years in such a position, the lower part of the well is liable to cave in, carrying with it the masonry and engine foundations. The likelihood is that this work will be rendered entirely useless, by the failure of the wrought iron in the caisson. In no case where reliable work is required does the mode of construction obtain, and a wrought iron caisson or cylinder of this kind, if used at all, is used only for a temporary purpose, the permanent work of either brick or stone masonry being carried up from the foundation on the inside of the cylinder.

The upper portion of the inside slopes of the embankment of settling basin seemed to be paved with a single course of brick laid on edge, without mortar. The concrete laid on the lower part of inside embankment slopes, appears poor and badly put on, and the stone masonry of a very inferior quality. We are unable to state the quality of the concrete laid over the bottom as it was covered with water, but presume it to be of the same class as we saw exposed. In fact the mason work of the entire basin is poor both in material and workmanship.

The embankments are but eight feet wide on top. This is a less width than is ever given to any work for impounding water, to the depth proposed here, except for temporary purposes. In regard to this basin, our judgment is that it would last but a short time, if it be made to perform the duty for which it was constructed, and the water line carried at an elevation, to secure the capacity mentioned on page 52 of report.

We consider the "distributing reservoir" on Tarbo's Hill, as even less reliable in its workmanship and materials than the settling basin. Here it is proposed to hold the water within high embankments, inadequately protected by a slope paving of poor material, laid in an inferior manner. This slope paving would offer but

slight impediment to the wash of the embankment provided the flow line was kept at or near its proper elevation. The embankments are but eight feet wide on top and should the water line be kept within two feet of top of bank (this is the elevation stated in the report as the high water line) the entire structure would probably soon be destroyed.

At the distributing reservoirs and also at the settling basin, the top of the embankments are plastered with a coat of cement mortar, about 1¼ to 2 inches thick. This would appear to be a useless expenditure. The plaster cannot possibly offer any resistance to the wash of the waves, nor for that matter can it be of use for any other purpose.

Sec. 17 further provides "and the reservoir or reservoirs from which the water shall be distributed shall in any case be on an elevation of at least one hundred and seventy-five feet above the city directrix of said city of Kansas, and the water therefore shall be distributed by the Holly system throughout the city."

A fair intepretation of the above would require that all the water to be supplied the city by their works should be first raised to the distributing reservoir, and from this point to be distributed throughout the city by the "Holly System." The plain intent and requirement of the contract, as set forth in the first part of, and in this extract from, Sec. 17 is, that two sets of pumping machinery were to be provided, one to be located at the source of supply, and the other to be located at the distributing reservoir.

This construction of the contract is borne out by the report of the engineer of the works who says, page 43 of report, "the first studies were directed to two pumping stations, one at the source of supply for filling the upper reservoir, the other at the upper reservoir for distribution." Following the above statement the engineer gives certain reasons for changing the construction of the works in this respect, and making such arrangement and disposition of the various parts as to result in a great saving in the running expenses of the department. It must be understood, however, that this result is obtained at a considerable sacrifice on the part of the city, for, had the original intent of the contract been carried out, two sets of pumping machinery would have been provided, located in different parts of the city and giving a very large, increased insurance against the danger of fires.

As now arranged, any break in the one engine leaves a major portion of the city without fire protection from these works. It must also be noted in this connection that the great advantage claimed for this departure from the contract is an advantage entirely on the side of the Water Company, as the city by the terms of the contract is required to pay a certain sum ($12,000.00) for the running expenses of the works, so that this change from the intent of the contract has been made to save the Company from any expenditure over this sum.

Without considering the question of which is the better of the two plans, it is plain that as built and arranged, the works do not answer the requirements of the contract as quoted above.

From the report (page 43) we also note that the supply of water for that part of the city called "lower town," is distributed from the reservoir in the ordinary manner, thus leaving this portion of the city depending entirely upon the pressure from the reservoir for its fire protection. This arrangement is also in conflict with the requirements of the contract as quoted from Sec. 17.

Another portion of the same section (page 21 of report) states that "the reservoir from which the water is distributed shall be of sufficient capacity to contain at one time at least ten days usual supply of water for said city and its inhabitants."

If we assume that at the time these works were completed the population of Kansas City amounted to thirty-five thousand and that the supply per capita should be not less than forty gallons (this is considerably less than is usually taken in a calculation of this kind), than to comply with the contract as to capacity and to be able to store a supply for ten days, the reservoir would be required to hold not less than 12,250,000 gallons.

Our measurement and calculations show that, with the flow line within two feet of the top of the embankment, the capacity of the reservoir is less than eight million gallons.

As before stated, our examinations lead us to the opinion that the construction of those parts of the work known as the "receiving cribs," the "receiving well" and the "upper" and "lower" reservoirs do not comply with the specifications; that they they are not first-class and of sound materials, and that, in this and other respects, they do not conform to the requirements of Sec. 17 of the contract.

The engine building, the engines and fixtures, and the pipe distribution may, we think, be considered as fairly complying with the contract as regards durability and permancy.

In regard to the ability of the works to perform the trial tests called for by Sec. 8 of the contract, we state that our calculations indicate that the test requiring the greatest capacity and strength in the various parts of the work is the second one mentioned, viz: (page 12 of report) "or eight streams as aforesaid through eight different hydrants in any part of the city, each throngh fifty feet of hose and an inch and a quarter nozzle to the height of one hundred and twenty-five feet."

We find that to perform this test, the pipe would be required to deliver about 3300 gallons of water per minute; the velocity, to furnish this amount, and the distance from the pumping stations, if the test be required at the points we indicate, would give a pressure of about lbs. to the square inch at the pumps.

If it be the desire of the city authorities to have the trial attempted, we would suggest the following places for the test, provided it is the wish to select to most difficult location, in order that one trial might answer for the entire city.

For the first trial we would take the fire hydrants located as follows:

No. 1—Independence Ave. and Holmes street; No. 2—Holmes street between Independence and Missouri Aves.; No. 3—Missouri Ave, and Holmes street; No. 4—Charlotte street and Missouri Ave.; No. 5—Charlotte and 5th streets; No. 6—Holmes and 5th streets No. 7—Cherry and 5th streets; No. 8—Locust and 5th streets.

For a second test we would select the seven hydrants located on Union avenue and one at the corner of Hickory and 10th streets. This second test is suggested in view of the statement given in the report (page 43) that the line of distribution pipe for "lower town" is only connected with the pumping main of the distributing reservoir, and that this section of the city depends for fire pressure upon the head of water due to this reservoir.

It is our opinion that the works are not constructed with sufficient strength and capacity and in such a manner as to successfully perform the trial tests as called for by section 8 of the contract.

We have made the following approximate estimate of the value of the works as now built. Our data for this estimate have been, from the nature of the case, very limited, while not claiming that the cost as here given is accurate, we believe the total to be a close approximation to the completed cost of the works. We consider the quantities and prices liberal, and in excess of rather than below the actual facts,

In making up the estimate of the pipe distribution we have used the quantities as furnished us by the City Engineer. The location and size of the pipes is shown on the accompanying map of the city. The fire hydrants we have located from the report of the Water Works Department.

Work and *material* of *receiving* cribs at river, completed		$3,500.00
Siphon Pipe,—furnishing and laying 1300 feet 24" pipe		9,750.00
Receiving Well—excavation, iron work and masonry of engine foundations and well completed		5,300.00
Engine building, boiler-house and chimney complete		15,500.00
Pumps, engines and machinery with valves and fixtures complete		50,000.00
Settling Basin, 1200 cu. yards earth excavation made into embankments, @ 40 cts.	$4,800	
350 cu. yds. stone masonry @ $6.50	2,275	
200 M Brick in slope paving @ $8.50	17,00	
1600 cu. yds. concrete @ $5.50	8,800	
Lumber, gravel and stone in filter complete	975	
Cement plaster on embankments	275,	19,350.00
Pumping Mains, furnishing and laying 6232 Lin. feet 20 inch pipe, complete		48,900.00
Distributing Reservoir, 20,000 cu. yds., excavation made into embankment @ 40 cts.	8,000	
2300 cu. yds. concrete @ 5.50	12,650	
1200 cu. yds. slope paving @ 1.50	1,800	
550 cu. yds. stone masonry @ 5.00	2,750	
100 feet tunnel @ 450	450	
Cross wall on tunnel and cement plaster on banks	3,90,	26,050.00
Pipe Distribution, furnishing and laying 2764 feet of 20-inch-pipe	18,434.48	
Furnishing and laying 956 feet 15".	2,350.92	
Furnishing and laying 18134 feet 12" pipe	62,859,32	
Furnishing and laying 10030 feet 10" pipe	278,23.06	
Furnishing and laying 18926 feet 8" pipe	39,789.76	
Furnishing and laying 17177 feet 6" pipe	25,971.24	
Furnishing and laying 1628 feet 4" pipe	1,790.80	
Furnishing and laying 1765 feet of 4" pipe not given by City Engineer	1,941.50	
Special castings, valves, fire plugs, 4" pipe for fire plugs, excavation through rock, etc.	21,500.00	
	$202,462.08	
	(say)	$202,500.00

RECAPITULATION.

Item 1. River work	$ 3,500.00
" 2. Siphon Pipe	9.750.00
" 3. Pump Well	5,300.00
" 4. Engine Building	15,500.00
" Engine and Machinery	50,000.00
" Settling Basin	19,350.00
" 7. Pumping Mains	48,921.00
" 8. Storage Reservoir	26,035.00
" 9. System of distribution	202,500.00
Total	$380.856.00

Add for real estate, engineering and contingencies, $14,144.00 giving approximate estimate as $395,000.00.

Should the city be satisfied with the quality of the water as supplied from the Kansas river, then in that case items Nos. 2, 4, 5, 7, and 9 may be considered as permanent and valuable work. The estimated cost of these items as given above amounts to (say) $350,000. In connection with this estimate, however, it must be remembered that the engine foundations are considered unreliable, from the fact that they are founded on the masonry laid around the well, which is liable to cave in by the failure of the wrought iron cylinder.

In case the present source of supply be abandoned then the only work that would be of real value and use to the city would be items Nos. 5 and 9, and in this case, the engines, etc., (Item No. 5) could not be valued at more than 50 per cent. of the estimate given above The two might be considered as worth about $233,000

THE BROOKFIELD TUNNEL.

Written for "Engineering News."

BY G. D. HERSEY, C. E.

In the following sketch it is proposed to give a somewhat detailed account of the purpose and construction of the Brookfield Coal Tunnel. It is located in Trumbull County, Ohio, and is a new opening to the coal mine called the Brookfield Slope,—one of the most extensive workings in the block coal regions of northeastern Ohio. The coal vein opened up by it lies in a range of hills forming the western boundary of the Shenango river valley, and at a depth of about 200 feet beneath the surface of their summit. The floor of the mine, like all others in this section, lies in undulations somewhat like a wrinkled carpet, varying in level from fifty to seventy-five feet. In the lowest and central portions of the seam the coal is from four to five feet thick, gradually thinning out to nothing on the upturned edges of the basin. The original opening was a slope, falling at the usual rate of one foot per yard. From the slope bottom radiate main and branch entries (with their hundreds of rooms) the aggregate length of which already is reckoned in miles. The slope was not put down on the lowest coal, hence the underground hauling has been uphill and expensive. The mine waters also drained *away* from the slope bottom necessitating special pumping machinery.

Heretofore the loaded mine cars, on being delivered at the top of the slope, were run along the brow of the hill for half a mile, thence down an inclined way, worked with wire ropes, also half a mile long, where the coal was dumped into railroad flats at the base of the

hill, and at a point not less than 130 feet below its original resting place. Thus the coal continued to be transported from the mine to the dumps by this cumbersome and expensive method, until the pumps and boilers became worn out, the incline got rotten and unsafe, and until the necessity of repairs, combined with the downfall in the price of coal, demanded a new opening and greater economy.

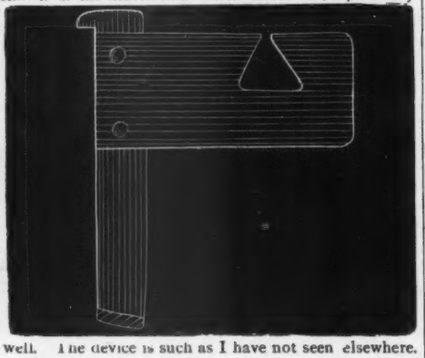
The great difference of level between the coal in the hill and the railroad in the valley, made it necessary to either cause the road to mount the hillside to reach the coal, or to carry the coal down to the road. There was no question, however, that the new opening should be a tunnel, and that it must furnish a natural drainage-way for the waters of the mine, as well as a route of exit for the coal itself. Accordingly in the location the first thing settled was to fix that point within the mine, which should be the inner terminus of the tunnel. As far as the present workings extend, that point was readily indicated by the flow of water in the mine drains. The inner terminus was then placed as far directly below this point as would bring it on a level with the bottom of the lowest coal (as shown by test drill holes) in those parts of the basin not yet developed. Having fixed one end of the tunnel, a preliminary survey showed the shortest route to day-light to be about 2800 feet, but the tunnel entrance would be high up on the hillside, at least a hundred feet above the railroads. Several schemes were advanced for overcoming this difference of level. It was proposed to extend the company's road from the place then occupied by the old chutes, and carry it up the hillside in switchbacks to the tunnel entrance. Another plan was to let the coal down from the tunnel mouth to the site of the chutes by an incline similar to the old one. A third scheme was a sort of compromise between the two preceding, and advocated raising the railroad tracks somewhat, carrying the loaded cars out from the mouth of the tunnel, at a slight descent, on a high trestlework, and dumping the coal down some sort of long chute, of which the design was never matured. For all of these projects were exposed to serious objections that ultimately destroyed them, along with several others of like character, and accordingly the "shortest tunnel" route was abandoned.

The plan finally adopted, and now carried into successful execution, is as follows: All the railroad tracks, weighing scales, etc., were allowed to remain unchanged by dumping the coal at the same spot as heretofore. Chutes as high as convenient to work (30 feet) were adopted, and a line of nearly uniform grade drawn from the top of the chutes to the inner end of the tunnel. Where this line struck the hillside was located the tunnel entrance. In round numbers it was 1,000 feet from the chutes and 4,000 feet from the inner end. The mouth is 72 feet lower than the inner end, the gradients being 1.71, 2.09 and 0.00 per hundred feet. In cross-section it is 8 feet at bottom, 6 feet at top, and 6 feet high in the clear, although in many places the rock has fallen, leaving the roof a pointed arch 8 or 10 feet high; 250 feet of the inner end is level and wide enough for two tracks, one being intended to hold the empty incoming cars, while trains of loaded ones are made up on the other.

The alignment of the tunnel is quite far from being straight, owing to several causes; some 400 feet of the inner portion lies partially in coal and partially in the underlying rock. As before noticed the floor of the mine is not level, and in this case a hill rose up sharply in the way, and it was thought best to drive around the point of it in order to take advantage of working in the soft coal, and avoid so much of the hard bottom rock. Secondly, three or four hundred feet more lay under the coal, with only a thin layer of rock between. Some old workings flooded with water lay in the way, and it was necessary for the line to avoid that; and, thirdly, the corner of lands not owned by the company lay across a direct line, which made another bend necessary. The final location being made accordingly, the center line, beginning at the mouth, runs thus: due west by a tangent 2,600 feet, thence deflects to the left, past corner of land spoken of, 37 degrees by a curve 390 feet in length, thence by a tangent, past flooded workings, of 620 feet, thence by a reverse curve around hill to the inner end.

Excepting a few feet at the mouth, the tunnel lies in rock the whole distance. About 130 yards at the inner end lies in a hard, light-colored sandstone, the remaining portion in a dark grey shale of varying toughness.

The work of removing the rock was begun at the outer face in June, 1875. When about one-third of the entire length had been driven, it was determined to hasten progress by driving from the inner end outwards. Consequently it became necessary to ascertain with great precision the direction in which to start the inner face. The only route by which a line could be run connecting the two faces was down the old slope and along the mine entries. Accordingly a traverse line was connected at the tunnel entrance with the center line of the portion already driven, and run thence up the steep rocky hillside for 1,400 feet, thence at nearly a right angle, a distance of 3,100 feet, to the top of the slope, thence down the same and along the main Dip and Scotch entries, by a very tortuous route, for 4,400 feet, to the inner face. Benchmarks consisting of iron plugs were inserted in the wall of the tunnel, and the the same route leveled from face to face. The part of the line lying in the mine entries was the most difficult to determine, with the requisite exactness, on account of its being broken up into such short sights and containing so many angles. The method adopted in running it was this: The stations were first marked and numbered on the roof, for the whole distance. In fixing them three mining lamps were used,—the rear one held at the station last fixed, and the other two so adjusted along the extremely crooked entry, that the distance between the two rear lamps was the greatest practicable, the station at the middle lamp marked, and the lamps moved on. Each station was placed precisely over a tie in the mine road, a hole drilled in the roof and filled with a wooden plug which carried an iron spud having a small vertical hole through a projection at its lower end. In the work of taking the angles a back sight and fore sight was used, similar to the one shown in the illustration, which served its purpose very



well. The device is such as I have not seen elsewhere. It consists of a square iron spike about eight inches long, headed and pointed. A piece of flat iron is riveted on to one side of it which has a three-cornered notch or aperture in it, with the upper corner open about one-eighth inch. Three such "sights" were employed. In using them a plumb-bob was hung to the spud in the roof and the sight hammered into the tie, so that the iron plate about bisected the angle at the station, and so that the open corner of the aperture was precisely under the point of the bob, which was then taken away and a mining lamp placed behind the sight, having the brightest part of its flame behind the open corner. The instrument being set up over the middle sight, with its plumb-bob where the first had been, the deflection angle was measured. The lamp flame was made large and bright and could be readily found through the glass, The open corner of the illuminated triangle was the point sighted at, but when the distance was so great that the cross hair more than covered it, still the line of sight could be easily adjusted with great accuracy by making the upper corner of the illuminated space on each side of the vertical hair appear at the same height. Each angle was read four times, and the average of the sum of the four readings taken for the truth. In turning the transit from back to foresight the telescope was revolved, but in turning from fore to back sight, the whole instrument was revolved on the lower spindle, thus eliminating, as far as possible, any instrumental defects. When an angle had been observed, the transit was set aside and the horizontal distance between the rear and middle sights measured with a steel tape to feet and hundredths. This done the back sight was taken up and fixed ahead for a new foresight, and the process repeated until all the angles and distances had been measured. Among the advantages derived from the use of these sights, it may be remarked that the transitman is not obliged to take anything on trust as to the correct position of the points he is looking at, and also when any given station becomes a back sight, precisely the same point is looked at as when it was a foresight.

These data being had, the alignment of the remain-portion of the tunnel was calculated, as also the proper angle to turn off from the inmost station in order to start the inner face in the right direction. The center line of the tunnel proper contains nine angles, and the traverse line thirty-four. Hence the accurate junction of the part of the tunnel driven from the inner face, with the part driven from the outer face, depended on a line containing forty-three angles in all, and nearly two and one-half miles in length. As the two faces were advanced into the rock, the center line was run forward by the same process as that described above. The permanent points fixed in the roof were kept back far enough from the face to be safe from the flying fragments produced by the shots, and temporary lines run forward to drive by. Finally, when the approaching faces broke through into each other, the center line was run together and the errors measured. The measured length of the tunnel was found to be shorter than the calculated length by one foot; the error in alignment was six inches. Below are given some of the principal features of this closed polygon:

Length of tunnel between terminal stations	4016.0
Number of feet driven from outer face	3193.0
" " " " inner "	823.0
Periphery of polygon closing at junction of faces	12997.6
Length of portion under ground	8438.0
Number of angles in polygon	43.0
Longest side of same	2735.6
Shortest side of same	40.0
Greatest inclination of any side	1 in 3
Extreme difference in el vation of any two stations	177.0
Amount of error in measurement at closing station	1.00
Amount of error in alignment	0.50
Amount of error in levels	0.30

On account of manner of driving tunnel, as described further on, no great accuracy in leveling it was called for, and they were made with transit in piecemeal as faces approached.

The ventilation of the outer portion was kept up by means of a furnace located at the bottom of a shaft sunk alongside the tunnel not far from its mouth. The short passage between the tunnel and furnace was closed by a partition and tight-fitting door (through which to supply the furnace with fuel). A wooden tube 16 x 20 inches in cross-section, made of four boards, had one end inserted in the partition. As the work advanced, the tube was extended along one side of the tunnel, its open front end being always kept within a few yards of the working face. Thus a ventilating current was drawn *in* through the tunnel against the working face, and *out* through the tube and up the shaft. The ventilation of the inner part was simply a branch of the general ventilating system of the mine and was kept up in the same way.

In the work of removing the rock, drilling was done by hand in the inside part, and by power drills run with compressed air in the outside part. Most of the portion driven by hand lay in sandstone. The manner of working as far as the coal reached, was to drive a heading in the coal, and blasting up the bottom rock in benches down to grade. After the tunnel went under the coal, the same process was continued except that for the last forty yards, the heading only was driven forward, in order to hole through, and thus the sooner finish pumping, as well as get better air. The part driven from the outer face lies wholly in shale, stratified horizontally, and having cracks or seams running through it (called "smooths" by the miners) every two or three feet in vertical distance. A heading, three to three and a half feet high, was started at the roof between two smooths, and were followed until they dipped a foot or so below grade, when the roof of the heading was broken through to another smooth, that followed in a similar manner, and so on. Three to five holes, four to five feet deep were bored in the face of the heading, charged with dualine and fired at once, the central holes leading by a few seconds. This method of working cleaned out the rock completely from floor to roof of the heading. The enlargement followed from four to five yards behind, the bottom being blasted up or the roof down as the case might be.

The crew engaged in removing rock at the outer face comprised, for twenty-four hours, 6 men in the heading, in shifts of 8 hours each, 4 men on the enlargement, in shifts of 10 hours each, and 2 men loading excavated rock into the mining cars, working 12 hours each. There were outside at the compressor, 2 engineers and also 1

blacksmith. The average rate of progress per day was 6.7 feet, making at the prices paid the men, the cost of *labor* only, for driving the tunnel full size, and putting the excavated material on to mining cars, very closely approximates $4.25 per foot. The material through which some parts of the tunnel extend, crumbled on exposure to the air, hence several hundred yards of it had to be timbered. In consequence of the work being done by the day instead of by contract, the data for estimating the exact expense is not at hand, but the entire cost of it as it stands completed ready for shipping coal is not far from $35.00 per yard

Twenty-one months is the total time employed in the execution of the work.

In conclusion it may be worth while to state, that with the exception of a bruised instep, by a fragment of rock falling upon it from a loaded car, the construction of the Brookfield tunnel has been completed without accident of any kind to any one in or about it.

EXPERIMENTS WITH BRICKS, STONE AND CEMENT.*

Translated by E. A. Rudiger, N. Y., for ENGINEERING NEWS.

The Royal School of Engineers, at Berlin, has been conducting a series of experiments on the strength of building materials, which has extended over a period of five years. The following are the principal results obtained by these experiments:

1. Bricks.

In the experiments, an entire brick was placed in the testing machine. The pressure per sq. inch was noted when the first crack occurred, and then the pressure which crushed the brick, the results of which are as follows:

a. Common bricks.

Number of sorts, 55. Number of tests, 843. Pressure at which first crack occurred—limits, 597–2672 lbs.; average, 1420. Crushing pressure—limits, 697–3200; average, 1765.

b. Hard burned bricks.

Number of sorts, 35. Number of tests, 850. Pressure at which first crack occurred—limits, 1114–3257 lbs.; average, 2175. Crushing pressure—limits, 1536–4395 lbs.; average, 2760.

The Department of Public Works of Berlin allows a pressure of 200 lbs. to the square inch to be taken where the best quality of brick and cement are used in building.

2. Natural Stones.

Six sorts of Diorite submitted to 43 tests; limits of strain at which first crack occurred, 8,178–19,100 lbs.; average, 12,415 lbs.; limits of crushing force, 8,820–21,820 lbs.; average, 13,755 lbs. Twelve sorts of Granite submitted to 133 tests; limits of strain at which first crack occurred, 3,300–14,365 lbs.; average, 9,785 lbs.; limits of crushing force, 4,437–15,575 lbs.; average, 10,200 lbs. Eight sorts of Grauwacke submitted to 30 tests; limits of strain at which first crack occurred, 9,100–12,160 lbs.; average, 10,113 lbs.; limits of crushing force, 9,743–13,725 lbs.; average, 11,065. Three sorts of Porphyry submitted to 45 tests; limits of strain at which first crack occurred, 5,050–6,160 lbs.; average 5,690 lbs.; limits of crushing force, 5,790–8,165 lbs.; average, 7,185 lbs. Seven sorts of Sandstone submitted to 125 tests; limits of strain at which first crack occurred, 870–7,282 lbs.; average, 3,985 lbs.; limits of crushing force, 1,189–9,815 lbs.; average, 4,780 lbs.

3. Cements.

There were also 3150 tests made with cements mixed in different proportions with sand. The following are the average results obtained in the tests of parallelopipeds 4" × 4" × 2¾" after hardening for 90 days. The strength was about the same whether the elements had hardened in the air or under water.

Pure cement—average strain at which first crack occurred, 4,125 lbs.; average crushing force, 4,708 lbs.. 1 part cement 1 part sand—average strain at which first crack occurred, 3,058 lbs.; average crushing force, 3,527 lbs. 1 part cement 2 parts sand—average strain at which first crack occurred, 2,375 lbs.; average crushing force, 2,773 lbs. 1 part cement 3 parts sand—average strain at which first crack occurred, 1,849 lbs.; average crushing force, 2,375 lbs.

Tests of mortar of the above proportions were also made to determine their resistance to a pull after hardening for 90 days, and it was found to be only about one-seventh of the resistance to crushing.

IMPREGNATED RAILROAD TIES.*

Experiments have been made on the government railroads of Hanover, and on the Cologne and Minden Railroad on the durability of impregnated railroad ties, and it was found, that of

Hemlock ties impregnated with chloride of zinc, 30 per cent. had been renewed after having been in use for 21 years.

Beechwood ties impregnated with creosote, 46 per cent. had been renewed after having been used for 22 years.

Oak ties which had not been impregnated at all, 49 per cent. had been renewed after 17 years' use.

Oak ties which had been impregnated with chloride of zinc, only 20.7 per cent. had been renewed after 17 years' use.

All the experiments were conducted under the most favorable conditions, viz., on good, pure and porous bedding.

Pieces of wood cut from impregnated ties in use at the expiration of the above periods, showed perfectly sound surfaces.

Observations made on the Northern Railroad of Austria (Kaiser Ferdinands-Nordbahn) have shown the following results:

Of oak ties which were impregnated, 74.48 per cent. had been renewed after 12 years of use.

Oak ties impregnated with chloride of zinc, 7.29 per ct. had been renewed after having been used for 7 years.

Oak ties impregnated with tar containing creosote, but 0.09 per cent. had been renewed after having been in use for 6 years.

Hemlock ties impregnated with chloride of zinc, 4.46 per cent. had been renewed at the end of 7 years.

Since 1869 the Northern Railroad of Austria use only oak ties which have been previously impregnated either with chloride of zinc or with tar containing creosote.

TO PRINTERS.

Among the many useful inventions to the craft brought out of late, the Palmateer proof press ranks as one of the best. We have had one in use for some time and do not hesitate to recommend it. The bed is 13¾ by 36 inches, perfectly planed. The impression roller is adjustable by means of set screws, and a light or heavy

impression can be obtained. Proofs can be taken from type locked in chase, on galleys or tied up. It is a simple, strong, durable press, and cannot but be useful in any office, particularly in country offices that have jobs of small auction bills in small quantities: such jobs can be done very acceptably on this press when the other presses are occupied. They are made by the Mohawk & Hudson Manufacturing Co. of Waterford, N. Y., and are sold for $30, about half the price of an ordinary proof press. Another size, large enough to take a half medium Gordon chase, is made and sold at $40.

LUBRICATION.

BY. PROF. R. H. THURSTON.

(From the Polytechnic Review, March 3, 1877.)

When two surfaces are rubbed together, however smooth they may be, a resistance is met with which is called friction (from the Latin *frico*, to rub). When a current of fluid moves in contact with the surface of a solid or with a mass of other fluid, a frictional resistance is also produced. In the former case, this resistance is due to the interlocking of minute asperities of surfaces and their forcible removal. The smoother the surface, the smaller these asperities and the less the resistance. In the second case, the resistance is due to the production of little eddies and of currents within the mass of fluid. It is seldom due to real rubbing of fluid against solid. Fluid friction generally produces a much smaller resistance than the friction of solids.

The effect of friction is to produce abrasion and wear of solids and, with both solids and liquids, to effect a waste of the power which is expended in producing motion. In both cases, all power thus wasted passes away in the form of heat in the proportion of one British unit for each 772 foot-pounds of work; and the existence of this cause of waste is objectionable, not only because of the waste of power, but because the production of heat, in such considerable quantities that it cannot be disposed of promptly by conduction to the neighboring solids or by radiation into space, results in so great an elevation of temperature at the rubbing surfaces that inconvenience and, sometimes, danger may arise by the heating of the lubricant and abrasion of parts.

Lubrication is the means usually adopted to reduce losses of power and the evolution of heat. It consists in the interposition, between the surface of contact, of substances having a lower coefficient of friction than the rubbing parts.

The coefficient of friction is a figure which expresses the proportion which the resistance to the sliding bears to the force with which the two surfaces are pressed into contact. A very low value would be 1-20, or 0.05; a usual value is 1-10, or 0.10; a very high value is 1-4, or 0.25. In some cases, as where journals are "cutting," this figure becomes very high, and even so great that, in many cases, the pressure imposed would be insufficient to produce sliding. Journals are sometimes "seized," and fairly welded or soldered into their bearings. Solid surfaces, dry, give about 0.20 or 1-5th.

Since both resistance and the development of heat are to be prevented, a good lubricant should have the following characteristics: (1.) Sufficient "body" to keep the surfaces from contact under the maximum pressure; (2.) The least viscosity consistent with (1.); (3.) The lowest possible coefficient of friction; (4.) The largest capacity for receiving and carrying away heat; (5.) A high temperature of decomposition: (6.) It should vaporize at high temperatures, rather than decompose and burn on.

In some cases, friction-rolls or wheels are substituted for rubbing surfaces, and the resistance is then "rolling-friction," which is not properly friction at all.

Lubricants may be either solid or fluid; the former are to be used on journals carrying very heavy loads, and the latter under light loads. Thus, graphite is used in the former case, and the oils in the latter. Tallow is used for pressures too great to be sustained by the oils; and for extremely light work as in watches, the most limpid of oils is required.

The solid lubricants, in the order of their frequency of application, are: tallow, lard, soap, metallic compositions, sulphur, graphite, asbestos, soapstone, lampblack, carbonate of lead ("white-lead").

The metallic compositions and some special solid preparations, as Babbitt or anti-friction metal and metaline, are permantly fixed in the bearings as a lining; and their effect is to substitute, for the hard, rigid and resisting surface of the metal of the bearing, a material which more readily adapts itself to the form of the journal and which has a lower coefficient of friction together with sufficient conductivity for heat. Many solid compositions are used on the bearing by interposition.

Graphite should only be used in the state of an impalpable powder and should be free from acid. A mixture of tallow, graphite, beeswax, and white lead, all together, or two or more together with water, is used for the journals of car-axles on railroads. A mixture of palm oil, tallow and lime-water, or of cocoa or palm oil with water and caustic soda, is still better. Eight parts of wax of the bayberry, and one of graphite, is excellent.

The fluid lubricants usually employed are the cheaper and more common fixed oils. (A siccative, or drying, oil is unfit for lubrication). Sperm, whale, lard, neats-foot and tallow oils; glycerine; olive, rape-seed, cotton-seed and other vegetable oils, and the heavy shale and petroleum oils are most used. Water is often used, but its value is that of a conveyor of heat rather than a reducer of friction. For wooden bearings under water, it is the usual lubricant.

In the "Palier-glissant" of Girard, the journal is supported upon a cushion of water, the waste from which is supplied by a force pump. Among fluid lubricants, sperm and lard oils, heavy shale oil and crude heavy petroleum are most used for heavy journals. The latter oils are rapidly superceding the more expensive animal

oils. Mixtures of the two classes are much used. The mineral oils have a great advantage in their freedom from tendency to oxidize and "gum" after remaining a considerable time on the journal or exposed to the air.

The pressure which can be borne by a lubricant depends upon the character of the frictional surface, as well as upon that of the lubricant itself, and also upon the velocity of rubbing. The maximum for solid lubricants is unknown, but it is probably proportional to the value of the elastic limit for the material or for that of the metal of journal or bearing—whichever may have the lowest value. For steel surfaces, lubricated with the best sperm oil and moving slowly, 1200 pounds per sq. inch has been found admissable. Under the pivots of spring bridges, pressures of several thousand pounds per square inch have been used. For iron journals, 800 pounds should never be exceeded.

The following formulas were made, the first two by the writer and the last by Prof. Rankine, respectively, to determine the maximum allowable pressures when the speed of rubbing was known:

$$P = \frac{60{,}000\ l.\ d.}{V}(1.)\quad p = \frac{60{,}000}{V}(2.)\quad p = \frac{44{,}800}{V}(3);$$

in which P is the total maximum pressure on the bearing in pounds, l and d its length and diameter in inches; V is the velocity of rubbing in feet per minute, and p is the maximum allowable pressure in pounds per square inch of longitudinal section of the journal. The first two formulas were determined by experiment upon the journals of naval steam engines, the last by observing the performance of locomotives. The exposure of the latter to dust compels the adoption of large surfaces. In many cases, engineers give a length of journal equal to twice its diameter, and find that lubrication gives no trouble. A better practice is to calculate the proper length of journal from the special condition of the case, as by use of formula (1) thus;

$$l = \frac{PV}{60{,}000\ d.}(4.)$$

For line-shafting, journals are often made four diameters in length by the best builders.

Messrs. King, Stivers and Price, of the United States Navy, reported the following as pressures on the lubricants named at a speed of 200 feet per minute: best sperm oil, 75 lbs.; lard, 55; best mineral oil 65; highest 30. They gave the following as the temperatures of congelation:—

Oil.	Temp. of incipient Congelation.	Temp. of Solidification.
Summer Sperm Oil....	66° Fahr.	56° Fahr.
Winter " "	48 "	36 "
" Lard "	40 "	25 "
Best Mineral "	43 "	20 "
Very light "	18 "	Below 0 "

Lubricants as found in the markets are variable in value, as in cost; and neither buyer or seller can usually form an idea of their real relative or actual intrinsic values. The most expensive are often found by test to be the least valuable. The appended tables give the results of experiments made to determine the relative and the cash value of oils in the Mechanical Laboratory of the Department of Engineering of the Stevens Institute of Technology.

The testing machine is illustrated in the figure. It was designed by the writer to determine pressures and velocities permissible, and to ascertain the coefficient of friction, the rise in temperature and the endurance of the oils. This machine, as now built in the machine-shops of the Institute, was designed, in detail, by Mr. J. A. Henderson, M. E. Class 1873, now of the United States Naval Engineers, and was somewhat modified and constructed by the Class 1877 and for the market. It was exhibited at the Centennial Exhibition by the Stevens Institute of Technology.

A journal, F, is made on the overhung extremity of a shaft carried in the two bearings B B, and is given certain special dimensions. This journal is grasped by brass boxes which are carried in a depending piece, K. They are forced against the journal by a screw which compresses a coiled spring with a pressure which is read off on the scale, N N. A weight at the lower end of this arm, I, gives it the necessary resistance to deflection. The angle of deflection is measured on the arc O P, in such units that the division of the figures indicated by the pointer, at any given angle of deflection, by the figure indicated by the other pointer on N N gives the coefficient of friction. A thermometer, O, gives the rise of temperature as the bearing warms up.

A standard weight* of the lubricant to be tested is placed on the journal F, which is driven at the speed chosen by the experimenter, or at that at which the journals on which the lubricant is to be used, are run. The pressure is similarly adjusted and, the machine once started, the observer, with watch and pencil in hand, records at regular intervals the temperature, the coefficient of friction, the pressure and the speed of rubbing. As the bearing runs dry, the temperature rapidly rises and the experiment is concluded. The observer enters on his record the length of the trial, and makes a memorandum of the peculiarities of behavior which have been noted during the trial. In the Mechanical Laboratory of the Stevens Institute of Technology, several trials are usually made under different conditions.

Experiments upon the value of lubricants were made by Amontons, as early as 1699, and by many physicists and engineers since. Coulomb, Rennie and Morin are the most generally recognized authorities. The following are the values of the coefficient of friction, F, with different lubricants, according to Morin.

CO-EFFICIENT OF FRICTION:—MORIN.

MATERIAL.	F.
Wood on wood without lubrication	0.25 to 0.50
" " lubricated with soap	0.04 to 0.20
Metal on metal unlubricated	0.50 to 0.60
" " " greased	0.20 to 0.25
" " " wet with water	0.25 to 0.35
" " " oiled	0.15
" " " freely lubricated	0.05

The following table represents the results of experiments on the best known lubricants as obtained by the writer, by the method above described, using great care in selection and driving the rubbing surfaces at a mean speed of about 750 feet per minute. This speed is very high and is purposely chosen; otherwise, the trials under moderate pressures might occupy days. The table is valuable as representing the *mean* value of trials of nearly all the good oils in general use.

AVERAGE OF COMMERCIAL OILS:—THURSTON.

Pressure.	Endurance. Minutes.			Rise of Temperature.	Co-efficient of Friction.
Per sq. in.	Ave.	Min.	Max.		
8 lbs.	82	17	411	167° F.	0.20
16 "	29	9	97	212	0.16
32 "	10	2	19	228	0.12
48 "	8	1	13	228	0.10

The following are the results of trials of fair samples of well-known kinds of lubricants at a speed of rubbing surfaces of 750 feet per minute.

CO-EFFICIENTS OF FRICTION AND ENDURANCE OF LUBRICANTS:—THURSTON.

Name.	Pressure.	Endurance.	Rise of temperature.	Co-effieient.
Sperm (Winter) Oil	8 lbs.	111 Min.	230° F.	0.13
	16 "	29 "	225 "	0.10
	48 "	9 "	195 "	0.08
" (Summer) Oil	8 "	165 "	170 "	0.13
	16 "	33 "	215 "	0.11
	48 "	7 "	265 "	0.10
Lard Oil	8 "	77 "	175 "	0.16
	16 "	27 "	250 "	0.12
	48 "	11 "	260 "	0.07
Neat's Foot Oil	8 "	106 "	205 "	0.15
	16 "	31 "	275 "	0.10
	48 "	6 "	190 "	0.10
Olive Oil	8 "	83 "	170 "	0.13
	16 "	41 "	245 "	0.10
	48 "	14 "	240 "	0.06
Cotton Seed Oil	8 "	107 "	185 "	0.16
	16 "	45 "	275 "	0.12
	48 "	12 "	310 "	0.07
Palm Oil	8 "	49 "	195 "	0.17
	16 "	15 "	235 "	0.13
	48 "	9 "	295 "	0.07
Castor Oil	8 "	45 "	160 "	0.19
	16 "	35 "	180 "	0.11
	48 "	11 "	375 "	0.07
Fish (Cod) Oil	8 "	40 "	200 "	0.15
	16 "	14 "	175 "	0.12
	48 "	9 "	220 "	0.07
Crude Mineral Oil.	8 "	129 "	105 "	0.10
	16 "	97 "	285 "	0.10
	48 "	5 "	270 "	0.10

Many compound lubricants and commercial oils of unknown composition have also been tested and the results entered on the Laboratory Record and a very extensive list has been examined for the United States Government, the results of which, for obvious reasons, cannot, with propriety, be given here. The above table is amply sufficient for all practical purposes, and for such pressures.

To obtain the best results, oils of little body should be supplied to the bearing with the greatest possible regularity and with equal care, to avoid too great and too small a supply. The least that will be safe is best. Heavier oils should be supplied more freely, and tallow should be fed as fast as the journal will take it.

Stevens Institute of Technology.
Hoboken, N. J.

* This weight is just enough to thoroughly wet the bearing and journal.

ON THE PROBABLE ERRORS OF LEVELING; WITH RULES FOR THE TREATMENT OF ACCUMULATED ERRORS.*

BY WILFRED AIRY, B. A., M. INST. C. E.

(*Continued from page 92.*)

In the ordinary way of leveling, probably the man who took the check levels would follow in the same route as the man who took the original levels, and if so he would have found no error at all; but in leveling from one end to the other, and in reversing the operation and leveling back again, these extraordinary results were pointed out. He therefore could not help thinking the engineers who informed the Astronomer Royal of the possible error of 6 inches in 34 miles were not so far from the mark as they might be supposed to be.

MR. LAW remarked that one source of error, arising from the varying temperature of the atmosphere increasing or lessening the length of the bubble, had not been referred to. From the way in which ordinary level-tubes were ground, it was almost impossible to insure their being such a perfect circle that the results obtained should be equally accurate when there was a short bubble and a large one occupying a much longer segment. For this reason, some years ago, Mr. Ramsden applied to a transit instrument a circular level, similar to a watch glass, which, being ground as true as a lens, gave more accurate results,

MR. BINNIE said he was rather surprised that what he had found to be the most difficult error to estimate or to account for had been entirely omitted. If a person leveling, as he had done, in a tropical climate early in the morning, had occasion to level from east to west, or *vice versa*, he would find the staff brilliantly illuminated at one stage, but at the other in comparative shadow. The result was that the eye did not readily accommodate itself to the difference of illumination, and it was curious, in levelings taken in the morning and again in the evening over the same ground, to notice the differences that would arise, due, as he was convinced, to a great extent to the unequal illumination of the staves when placed in those extreme positions. He had a line of 10 to 12 miles, running east and west, carefully leveled with the best instruments by the best native observers, and was surprised at the errors taking place in that particular line. He tried it as an experiment on another arbitrary line running north and south, and the errors taken in the morning and evening, the usual time for leveling in India, almost disappeared. No doubt practised observers, eliminating their personal errors, would have reduced the error almost entirely, by varying the direction of the line with the illumination of the staff.

MR. REDMAN suggested that the greater error shown for the English levels might possibly arise from the small amount of time usually allowed for such operations in this country, and the rough-and-ready way in which they were generally carried out. Some few years back he took check levels with the late Mr. Augustus Hamilton Bampton for the permanent levels of the Plymouth and Tavistock railway. Mr. Bampton had an expensive, large, heavily-mounted instrument, while he used a small Simm's dumpy. On comparing notes the error between Plymouth and Tavistock amounted to 4 inches over 18 miles, which would give a value of 0.0185 foot per mile, corresponding very nearly with the third value set down for India in Table II. A series of levels had been taken in 1830 by Colonel Lloyd, R. E., whose levels were usually accepted as undoubted, and the benchmarks had been connected generally with the Ordnance Survey; the result then arrived at showed a difference of level between high water at London Bridge and Sheerness of 2 feet, whereas it was undoubtedly nearly 4 feet at that period as it was now. The discrepancy arose from the fact, that the levels were connected with a series of tidal observations that gave a higher range for the tide at Sheerness than was actually the case.

MR. R. H. HILL observed that there seemed to be a

possible error which had not been alluded to. Though certainly not a practical one for civil engineers generally, it might possibly come within the scope of an Astronomer Royal. In leveling from the equator to the pole, he imagined the line of sight was a tangent to an ellipsoid curve, and therefore that the offsets of that curve would not be equal. In leveling parallel to the equator the offsets would be strictly equal. What the amount of that error might be he was not in a position to calculate, but perhaps Mr. Airy, in his reply, would say if it was a calculable one in 400 or 500 miles, for instance of leveling; and if so, whether he had taken it into account in the results he had given.

Mr. ELWES said one source of error which might possibly throw some light on that accumulating error, was the fact that, in leveling operations, two observations were always taken from the same staff, and that there was a perceptible interval of time between the first and second. Now, the weight of a leveling staff was not altogether to be neglected, and it had occurred to him, that the weight of the staff pressing upon the point of support, espccially where a peg had not been driven in to carry the staff, might possibly lower its position, so that at the second reading it would be a trifling amount below what it was at the first. If ten observations were taken in a mile, and the error amounted only to 0.001 foot at each observation, it would give an accumulating error of 1 foot in 100 miles, which in the Irrigation Department in India, was considered the maximum difference to be allowed. This would equally apply, whether the fore staff was read first or the back staff, because in either case the second reading would be taken at an appreciable interval of time after the first reading, and in that interval, more particularly if the staff holder, in reversing the staff, lifted it up and let it fall, there might be a slight lowering of the point of support.

Mr. A. GILES remarked that his early days of leveling were connected with the old staff, when surveyors did not read their figures, but trusted to the staff-holder to move a vane up and down, and were dependent upon the accuracy of that man's movements for reading off the staff. He could not help feeling, as a practical leveler, that there were errors mentioned in the paper which no engineer in leveling for a canal, or waterworks or railway, would ever take into calculation. In the paper the maximum distance of the staff was put at 5 chains, and in India at 10 chains, but when accuracy to 0.001 foot was required the stations must be closer, since with an ordinary level the staff could not be read off to that nicety at 10 chains distance. If levels of such startling accuracy were required, the pickets must be firmly driven, nicely polished, and leveled off; they must be measured exactly equidistant from the level, and the engineer must never think of going out when there was the least breath of air to ruffle the instrument. There must also be plumb-bobs, and bubbles to keep the staff level. If an ordinary leveler were to be encumbered with these impediments he would never get through his work. He had frequently leveled 12 miles a day. He obliged his men to put stones down for pickets, and not trust to the picket being carried down ½ inch by the simple weight of the staff. In going up or down an incline it was true the back stations in going up would be farther off than the fore stations, and if the level was not perfectly in adjustment, there would be a slight local error at the top of the incline, but, by the same rule, in going down again that error would be corrected. He maintained that for all practical purposes an error of only 1 inch in 10, 20, or thirty miles was quite enough for any engineer to work to. No doubt, theoretically, it would be desirable to obtain absolute accuracy, but when he heard of a series of scientific levels having been taken between the Bristol Channel and the English Channel, which showed a difference of more than 1 foot, he should like to know on which line the error lay, and how it was corrected. No ordinary leveling by an instrument was exactly accurate, and the only course to prove its accuracy would be to take a series of levels from one side to the other and back again, and then to take the mean. He believed any practical leveler of the present day, with ordinary instruments, would be able to get much nearer than 1 foot of difference between the Thames and the Bristol Channel.

Mr. BARLOW said if he made use of the term "error," he should have said "difference." The matter was gone into with extreme care, and probably the mean of the two sets of measurements was more like the correct level.

Mr. J. N. SHOOLBRED stated with reference to the apparent discrepancies appearing sometimes in very careful leveling, a case which lately came under his notice in the neighborhood of Liverpool, where the levels had been conducted with the greatest precautions: he referred to the datum of the Ordnance levels for Great Britain, which had been fixed at Liverpool. There was also another of long standing in use there, called the "Old Dock Sill" datum. Though several well-known engineers had at different times leveled and compared the two systems, one would be surprised to find how much discrepancy there existed, amounting at least to between 3 and 4 inches, as to the actual difference of level between the two points of reference. This matter had been brought before the last meeting of the British Association at Bristol, and a committee, of which Sir William Thompson was chairman, was appointed to find out the real cause of the discrepancy.

Sir JOHN HAWKSHAW, Past-President, thought a little confusion had arisen in the discussion of this question; the point was not altogether what was sufficiently accurate for railways and ordinary engineering works. For a railway it could not signify much if in a length of 70 miles there was a difference of 1 foot in the levels. But there were operations where it did signify. For instance, the Ordnance levels were referred to the mean level of the sea, and to other standards which had to be ascertained; but if this mean level of the sea could not be ascertained with precision it might lead to considerable errors in some operations. With reference to the tides, although it was of importance to know what was the mean level of the sea round the coast of England, and in other and more distant places, he doubted whether it had yet been accurately ascertained. It was to purposes of that kind that papers similar to the present had an important bearing. Going from that portion, he might mention one or two things with regard to practical leveling. In the first place, he believed, if his memory did not mislead him, with regard to levels which he had to take a long time ago, he was able to get a little nearer than some of the differences referred to; but that was very much a matter of instruments. He had a large instrument made by Troughton with which he could read to 1-10 inch, at much more than 10 chains off; he believed to 1-10 inch nearly 1-4 mile off. He might mention a somewhat curious instance of comparison betwixt ordinary rough leveling and leveling with more scientific instruments. which occurred to himself when he had occasion to go to Saxony, now forty years ago, in order, in conjunction with Mr. Walker, to lay out the Leipsic and Dresdon railway. The then Astronomer Royal for Saxony had been engaged, before he commenced his operations, in making a section of the country. He had been three months in getting from Leipsic to Wurzen, about 14 miles; he used a large astronomical instrument, with which angles of depression and elevation were taken, and all the corrections that an astronomer could apply were made. When he got out to Saxony he was told that those operations were being carried out, but replied that it would be sadly too slow for his purpose, for he could not remain there above three months, the distance being about 70 miles. Starting, he ran over with a spirit-level from Leipsic to Wurzen in three days. They were only tried levels, but he wished to see the best line of country. He remembered quite well the difference betwixt the Astronomer Royal and himself was only 7 inches, showing that for common engineering purposes levels did not, perhaps, require to be taken with that minute care and accuracy which were certainly necessary for other operations.

Mr. ARTHUR WOODS said he had leveled several thousand miles in Australia. On one occasion, for the New South Wales Government, he had occasion to run a line of levels 300 miles, which was checked independently by the Victorian Government. In the 300 miles the difference was only 0.12 foot. He put in benchmarks every mile, and for any difference over 0.05 foot, used to go over the ground a second time. Iron tripods were used to rest the staves on, and he should have considered it very bad leveling to have had an error of 0.28 foot in 5 miles.

To be continued.

We understand the C. & T. R. R. dock, at Toledo. Ohio, was let at $55,000

CORRESPONDENCE.

PHILADELPHIA, *April 12, 1877.*

EDITOR ENGINEERING NEWS:

SIR.—I should like to have the ideas of some of your correspondents, upon points in proportioning the sizes of a sewer for a main drainage receiving accessions at points on the line, necessitating an increased sectional area or velocity.

1. Where the velocity remains the same and greater sectional area required, should the increase in the vertical diameter of sewer be made at the top or bottom?

2. Where greater velocity allows of a decreased sectional area, should the vertical diameter of sewer be decreased accordingly; if decreased, should it be made at top or bottom?

3. Should the theoretical velocity be as nearly uniform as possible on the whole line; should it gradually increase towards its outlet; or may it vary at different points?

4. Should the maximum capacity of the sewer be calculated from the full sectional area;

The above to apply to sewers having ventilators and free at outlets. J.

MEXICO, MO, *April 14, 1877.*

EDITOR ENGINEERING NEWS:

SIR.—In your issue of March 31st, I notice an extensive article from Mr. Morrison, evoked it seems by your editorial concerning a certain query as to the manner in which certain strains would pass under certain conditions that have already been stated. The query was put, as originally stated, for the purpose of provoking discussion, and I was just a little disappointed, when, receiving Prof. Greene's kind and explicit letter on the subject. I thought the object of my query had failed. Had the Professor's letter been published I shall always think it would have been quite beneficial to many of your young readers, and I presume, that realizing something of this, later, you wrote your editorial. If, as the "original querist," I should be allowed an assent to or dissent from the answers to my query, I would like to note some of the points in Mr. Morrison's letter—the greater part of which have already been predisposed of in your editorial.

The practical results reached by Mr. Morrison's mode of reasoning are the same as those deduced from considering the strains as passing through the web members, but to my mind, do not seem to be simple and so easy of application, especially in determining the position of the necessary counters. It was fortunate for Mr. M's showing of the 3d panel without diagonals that the relation of load and dead loads were such that there was no vertical or shearing stress in this panel and hence, under the circumstances, no diagonals necessary. Had 24,000 lbs. say, been substituted for the 7,200 lbs. counters would have been necessary in each panel, and *at least* a *portion* of the ⅙ would be seen straining each member. As to diagonal ties not being capable of transmitting tension, as set forth in proposition 6th, it is certainly admitted that they may be compressed to the extent of their tension, and after this any other tendency to distort their panel in that direction, must be received by a counter. For instance, a tie under 1,200 lbs. tension is just as capable of transmitting that amount of compression as the strongest iron column. With regard to its being a portion of bridge weight and not of the live load that is transmitted to the farther abutment, it is a mere matter of name. At any rate it is an additional amount of weight equal in this case to ⅙ of the live load and beginning in its effects at the 1st joint. If again we use 24,000 lbs. for 7,200 lbs., a portion of it *must* be considered as passing; for all the dead load of the bridge—placed at the farther abutment, is not sufficient.

Mr. Morrison's proposition 8 touches another subject, capable of being viewed in more than one light: "Two stresses cannot pass in opposite directions in the same panel at the same time." If a panel should have a single diagonal member (capable of bearing each kind of stress), subjected to say 1,000 lbs. tension, from one cause (say panel weight to the right of it) and 500 lbs. compression from another (say live weight to left of it), each considered separately may produce these respective effects beyond the point of meeting and yet leave the member in which they meet under a tension of only 500 lbs. They neutralize each other to the extent of the smaller, but *neutralized tension, philosophically speaking, is compression, and vice versa.* Any one in the habit of analyzing the Warren or triangular girder, will recall how convenient it is to consider strains of different kinds as passing each other in a certain member and performing effects beyond the point of meeting. When each stress on said member, due to every weight is considered, the algebraic sum (calling one kind plus and the other minus), will give the kind and amount of that kind of strain that the member is under for those conditions. The member is left under only one kind of strain, but that *strain alone* furnishes no clue to the amount, kind, or direction of the strains of which it is the resultant. Very respectfully,

J. N. BASKETT.

P. S.—Your editorial concerning a text-book on Engineering is on the right subject. I have searched for such a book but cannot find any to suit. A review of all previous mathematics is necessary with most of our treatises. J. N. B.

ARCHES;

CONSIDERED GRAPHICALLY.

[Copyright 1877.]

(*Continued from page 82.*)

46. For any position of the weight plot the value of y_0 and draw the curve of equilibrium. Then draw the two lines from the extremeties of the load line W, parallel to the sides of the curve, and thus determine H and the two vertical components of the reactions, which vertical components will be the same as for a beam supported at its ends. But, from the simple relations of the similar triangles A G C and 031, as also B G C and 032, we may write a general expression for H, if desired. Thus we have

$$y_0 : c - b = P_2 : H, \text{ or } P_2 = \frac{y_0}{c-b} H;$$

$$y_0 : c + b = W - P_2 : H, \text{ or } W - P_2 = \frac{y_0}{c+b} H.$$

Eliminating P_2 in the second equation by substituting its value from the first, we get

$$W - \frac{y_0}{c-b} H = \frac{y_0}{c+b} H, \text{ or } W (c^2 - b^2) = 2 c y_0 H;$$

$$H = \frac{c^2 - b^2}{2 c y_0} W = \frac{1 - n^2}{2} \cdot \frac{5 (5 - n^2)}{32} \cdot \frac{c}{k} W. \qquad (12.)$$

This value also will apply to a load on either side of the center.

It will be observed that, to obtain this value of H, we have simply to divide $\frac{1-n^2}{2}$ by the factor which multiplies k in (11.), and thus get the factor by which $\frac{c}{k}W$ is multiplied. The numerical values of this factor are worth obtaining, as, the computations once made, the results apply to every rib with pivoted ends. Let the span of the arch be divided into any convenient number of equal parts, and, for illustration, suppose that the number is ten, as shown in the figure; let a weight W be placed successively over each point of division, being supported by the rib. The calculation may conveniently proceed in the following manner:—

Find the different values of y_0, for different positions of W, by equation [11′.]. Then compute H by [12.] The calculation and results are given below; the curves of equilibrium and values of H are represented in Fig. 10, for one half of the arch. As n^2 is positive, whether n is + or −, the values of y_0 and H will be symmetrical on each side of the center.

VALUES OF y_0 AND H.

$n = \frac{b}{c} =$	0	.2	.4	.6	.8	
$5 - n^2 =$	5.00	4.96	4.84	4.64	4.36	
$5(5 - n^2) =$	25.00	24.80	24.20	23.20	21.80	
$\frac{32}{5(5-n^2)} =$	1.280	1.2903	1.3223	1.3793	1.4679	k

Multiply these factors by k to give y_0.

$\frac{1-n^2}{2} =$	0.50	0.48	0.42	0.32	0.18	
$\frac{1-n^2}{2} + \frac{32}{5(5-n^2)} =$	0.3906	0.3720	0.3176	0.2320	0.1226	$\frac{c}{k}$ W

Multiply these factors by $\frac{c}{k}$ W to give H.

For any other desired division of the span another such table is easily computed.

47. If every point of division were loaded with W at the same time, the value of the horizontal thrust would be equal to the sum of the H's for each load, that is, the factor in column 0 plus twice each of the others, and the sum multiplied by $\frac{c}{k}$ W; we thus obtain $2.479 \frac{c}{k} W = H$. If a *truss* were uniformly loaded horizontally, the bending moment at the middle would be one-eighth of the total load multiplied by the span, or, for a truss of ten panels, with W = one panel load,

$$M = \frac{10 W \cdot 2 c}{8} = 2\tfrac{1}{2} c W;$$

and the tension in the lower chord, or the compression in the upper chord, would be found by dividing this quantity by the height of the truss, K. If the span of the arch just treated had been divided into twenty equal parts, the value of H, for loads at all the points of division, would have been $4.990 \frac{c}{k} W$. The truss, as before, would give $\frac{20 W \cdot 2 c}{8} = 5 c W$.

We thus see that the funicular polygon, for a number of equal loads, equidistant horizontally, on a parabolic rib, gives a value of H approximating closely to that for a uniform load on a truss of height k, coming nearer as the loads increase in number, and agreeing when the load is continuous, when the funicular polygon will coincide perfectly with the parabolic rib and give the same horizontal thrust as we are accustomed to in the bowstring girder under a maximum load.

48. We may now, if we please, compute values of the bending moment M for numerous points, when W is placed on any one point. If y denotes the ordinate from A B to the inclined line, and z the ordinate of the parabola from any point D, the bending moment may be written

$$M = H [y - z]. \qquad [13.]$$

If put in this form, it will be seen that, in the neighborhood of y_0, M will be positive. As the arch has a tendency to move away

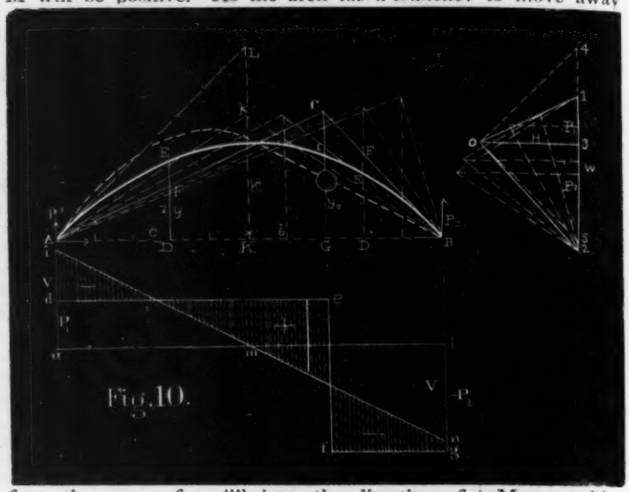

Fig. 10.

from the curve of equilibrium, the direction of + M, or positive bending, will coincide with that for a beam supported at its two ends, tending to make the arch flatter, and, so far as bending is concerned, causing compression on the upper side and tension on the lower side of the rib. As this is the most familiar flexure of a beam or truss we have chosen to consider it as positive. When the curve of equilibrium runs inside of the centre line of the arch, — M will produce the opposite effect.

The ordinates y and z can be readily calculated from the figure. Thus, if the weight is at 4-10 c from the middle of the span, we have found y_0 to be 1.3223 k. If the span is divided into ten parts, the number of divisions on one side of the weight being seven, y will be successively 1-7, 2-7, 3-7, etc., of y_0; on the other side y will be 1-3 and 2-3 of y_0. The sum of the denominators always equals the number of divisions, and the fractions run from both ends up to unity. After finding the first y at each end, simple addition obtains the others, and the row is checked by obtaining y_0 at the proper point. As stated in § 45, the ordinate z is proportional to the product of the segments into which it divides the span, or, if it is at a distance nc from the middle, we have

$$z = (1 + n) c (1 - n) c \cdot \frac{k}{c^2} = (1 - n^2) k.$$

The factors by which k is to be multiplied can therefore be at once obtained by taking the *decimals* which are found in the second line of the table for y_0, § 46.

49. The computations may then be set down in the following shape, viz.:—

VALUES OF M. y_0

Point of Division.	1	2	3	4	5	6	7	8	9	
$\frac{y_0}{7} =$	.1889	.3778	.5667	.7556	.9445	1.1334	1.3223	.8815	.4488	$= \frac{y_0}{3}$
$z =$	.36	.64	.84	.96	1.00	.96	.84	.64	.36	
$y - z =$	−.1711	−.2622	−.2733	−.2044	−.0555	+.1734	+.4823	+.2415	+.0808	k

Multiply through by $H = 0.3176 \frac{c}{k} W$.

	−.0543	−.0833	−.0868	−.0649	−.0176	+.0551	+.1532	+.0767	+.0257	c W

Multiply these factors by c W to give M.

With the explanation already given, this table can be readily understood. The letter y_0 is placed over 7 as a convenience, to show that the value y_0 occurs at this point of division. If the load is on the right of the center, these numbers run from the left abutment; if the load is on the left of the center, they must be considered to run from the right abutment. It is worthy of notice that, while the value of y_0 is independent of the span of the arch, M is independent of the height of the arch.

(*To be continued.*)

COUNTRY HIGHWAYS.

One of our correspondents has expressed the desire that we might find time to write something about common roads. There are in our last volume several articles, contributed and selected, which bear directly upon this subject, but, as this volume is out of print it will be of little use to refer our numerous new subscribers to its pages. The book of Gen. Gillmore's, published not many months ago, contains very much useful information in this direction, and we have also meditated spreading upon our pages one or two excellent essays which are not now readily accessible.

This is the time of year when the usual spring repairs are made upon the highways which, as the frost comes out of the ground, make very plain to the traveling public where their weak points are. They are put in such a shape as to look easonably well for the present, and during the dry time of summer, all the money which is appropriated for such purposes is expended at once, and they are then left to take care of themselves until another town-meeting, in the next spring, appoints a new overseer of highways and places some means at his disposal. There are some points in regard to our usual methods of making and renewing roads to which attention cannot be too often called, and we shall be glad to aid in some slight degree the adoption of a better practice.

In making a new road it is very poor economy to leave the natural surface soil or vegetable loam in place, covering it perhaps with a layer of good gravel. The loam is moderately retentive of water, will work up through the gravel and form mud or dust, in a wet or dry time. Water is at the bottom of about all the trouble with a road. If the foundation is well drained, and the surface is so consolidated that rain will run off before it has time to soak in, we shall have a good roadway in all weathers. One great object of the layer of large stones which forms the bottoming or foundation course of a Telford road, the very best highway possible without pavement, is to permit the thorough draining away of all water. Another object is to distribute the pressure, which is concentrated by the wheels of a loaded wagon on a very small spot at the surface, over so large an area at the base that ruts and hollows shall not be formed. Ruts retain rain-water which must necessarily soak into the surface, softening it and allowing the wheels to cut still deeper through what ought to be a hard crust.

If stone for under draining cannot be procured, small drains at frequent intervals across the road ought to be introduced, built of such materials as are reasonably cheap and accessible. A considerable sum of money, judiciously laid out on first construction, is a good permanent investment, for it can be made to produce a *permanent way* worthy of the name. The saving in annual repairs will warrant the capital outlay. Of course it is desirable that the road should be raised somewhat above the surrounding level to secure drainage, but if this is only accomplished by digging ditches at each side, the material from which makes the road, while these ditches have no outlet but stand full of water during the winter and spring months, these trenches are of no use; for the water is naturally at the same level below the road as in the ditches, or even higher from the absorbing power of the earth, and the material is such that it readily poaches up and wheels go in to their hubs. Then the neighboring fences are called upon for contributions, till sometimes the mudholes are almost corduroyed with rails. By the way, corduroy does not make so bad and rough a road, if the covering material is up out of the way of the water, and will bind enough not to cut through.

The ordinary plan of allowing the working out of taxes on the highway, pretty much as the notion takes each one, under no, or very little, skilled supervision, is an excellent example of "how not to do it." The plow and scraper are all the tools needed. The sides of the road are broken up with the plow, the soil, sods, and washings from the road, consisting of old soil previously taken from the ditches, materials ground to dust under the traffic, droppings, etc., are scraped from the sides to the middle, well rounded up to let the water run off, and left to be consolidated by the wayfaring public. Nobody, after a moment's reflection, would expect such a road-bed to keep in shape or carry heavy weights. A mistake is made in giving so much convexity, as is often the case, to highways. The traffic is driven to the middle of the road, so that the wear is concentrated in a narrow track, and ruts are speedily formed, in place of being distributed over the whole of a gently sloping surface. That country roads are patched up and left in this shape is probably due to the fact that ordinary supervisors give little thought and study to the matter, but follow implicitly the bad precedents of their fathers.

Broken stone makes an excellent and durable surface when once consolidated, although the process of consolidation is hard on vehicles when the public have to do it. Road-rolling can only be expected in large towns. Sprinkling and a slight dressing of gravel hastens and assists the binding. MacAdam did not advocate any preparation of a foundation, but Telford believed in making a dry and durable substratum of stone; the road by the latter method is much the better. It is wrong to add gravel or broken stone to a road surface without first removing the mud and refuse; this mud works among the stones and prevents their binding. Broken limestone and sandstone are not so good for a coating of roads as is a harder material, for they wear round under the wheels and the pulverized portion makes mud and dust, hindering also the binding as before. Granite and Trap make good broken stone. The softer stones, however, do well for the foundation course.

It would be an excellent thing for our roads if broader tires for heavily loaded wagons should come into use; the wear of the road would be much decreased and, while the tractive power required would not be increased but rather diminished, on pavements, it would be very much lessened on country roads. Good roads are a direct benefit to all who use horses, a credit to any town, and an indirect benefit to everybody.

If any of our readers who have had experience in making highways can inform us whether it is possible to make a good, durable road, in alluvial soils, such as prairie earth, where stone and gravel are not to be had, and how it is to be done, they will confer a favor on many of the subscribers to this paper.

We have sketched, rather briefly, a few of the points which have occurred to us as worthy of notice in this connection, and shall be glad to hear from those who have had experience, and can give us facts, items of cost, and statements of success.

ERRATA.

In our article on "Strength of Columns," in the last number of the NEWS, 1st column, 29th line, for *number supplying* read *numbers applying;* 21st line from bottom, for *and* read *in;* 14th line from bottom, for *regular* read *rectangular;* 2d column, 17th line, omit the first sign of equality, leaving the expression $n f' b h^2 = M$; 31st line, for *as long so* read *so long as.*

As the communications from the associate editor cannot be revised by him, he is obliged to depend upon others for the correctness of the proofs, and we regret that these errors escaped the eye of the proof-reader.

CIVIL ENGINEERS' CLUB OF THE NORTH-WEST.

Owing to the absence of so many members in attendance at the Convention of the American Society in New Orleans, and particularly on account of the absence of the Committee on the adoption of the Metric System, who were to report at the May meeting, there will be no meeting of the Civil Engineers' Club of the Northwest in the month of May.

L. P. MOREHOUSE, *Sec.*

CO-ORDINATE SURVEYING.*

BY HENRY F. WALLING, C. E.

RELATION OF SURVEYING TO GEODESY.

Surveying is commonly defined as the art of measuring, laying out and dividing land. The similar but more comprehensive art of geodesy applies to the earth itself, as indicated by the etymology of the word, which is derived from *γη. the earth* and *δαιω, I divide.* Its objects are, the determination of the form and dimensions of the earth and of its different portions; the continents and islands with the lakes, rivers, mountains, civil divisions, etc. Its processes, like those of astronomy, upon which, indeed, it is to a considerable extent dependent, require instruments of a high degree of precision and mathematical computations of great refinement.

* From the Transactions of the American Society of Civil Engineers.

GENERAL GEODETIC CO-ORDINATE SYSTEM.

In the operations of the great geodetic surveys of the world, including for our own country those of the United States Coast Survey, positions are finally determined by referring them to co-ordinate planes. The plane of the earth's equator forms one of these co-ordinate planes and that of an assumed standard meridian another, the origin being the center of the earth or the point where the earth's axis cuts the equatorial plane. The position of any geodetical point is fixed by determining the direction in space of its radius vector, as referred to the two co-ordinate planes, and the length of this radius vector. Its angle with the equatorial plane measured on either side is the latitude; the angle of its projection upon the equatorial plane with the meridional plane, measured in either direction around a semi-circle is the longitude, and the length of the radius vector, or rather its excess over that at the level of the sea is the altitude of the place determined.

VARIATION BETWEEN OBSERVED AND TRUE LATITUDES.

Owing however to the spheroidal form of the earth, latitudes as observed and recorded do not exactly represent the co-ordinate angles or true latitudes. The observed latitude of a place is the angle made by a normal to the earth's surface at that point with the equatorial plane. The co-ordinate angle could easily be computed from the observed latitude if the earth were an ellipsoid of revolution of known eccentricity.

IRREGULAR FORM OF THE EARTH.

But it has been found that this is not the true form of the earth. The equator, and probably all parallels of latitude, taken at the level of the sea, vary more or less from true circles, indicating a want of homogeneity in the materials which make up the earth's volume. Longitudes are measured by noting the earth's rotation angles on the undoubted assumption that its angular velocity is strictly uniform. By noting the difference in time between the passage of a normal to the earth's surface at any particular point, and of another normal at any point on the standard meridian, across a celestial meridian, we obtain an angle which is called the longitude of the former point, the longitude of the standard meridian being zero. Irregularities in the form of the earth of course change the direction of normals to its surface, and require, both for latitude and longitude determinations, corresponding corrections.

ITS DETERMINATION A DIFFICULT PROBLEM.

In consequence of these irregularities, the problem of determining the exact form of the earth is an exceedingly difficult one. Instruments of the highest degree of precision must be used by skilled observers, and the combined results of a vast number of careful observations over widely extended areas must be subjected to the most refined mathematical investigation before its full solution can even be approximately obtained.

PROGRESS MADE IN ITS SOLUTION.

Its investigation has been going on however for one or two centuries; and very fair progress has been made. The great national surveys of the world have been conducted by men eminently qualified for the task, and the results of these surveys so far as completed, seem to approach quite near to the attainable limits of accuracy.

UNITED STATES COAST SURVEY.

This is particularly the case with our own Coast Survey which is probably unsurpassed, if not unequalled in precision and general accuracy. Our country, however, has thus far failed to realize some very important advantages which might be derived from these Coast Survey operations, although they have been sufficiently carried out to render them available over considerable portions of the country.

OBJECT OF THIS ESSAY.

It is the object of this paper to point out a simple method by which the high degree of precision which accompanies the Coast Survey work may be made available in the ordinary operations of land surveyors and civil engineers in those districts over which the Coast Survey triangulations have been carried, and at the same time to call attention to the importance of an extension

of these triangulations over the entire country, either by the general or by State governments. One of the disadvantages of our peculiar confederate form of popular government is an apparent inability of disposition to undertake works of acknowledged and eminent utility, unless they are popular with the masses or with those who control the machinery of elections. It is certainly the experience of foreign countries, including several less wealthy and prosperous than our own, that these surveys are many times more valuable than their cost, in the aid they afford to the carrying out of internal improvements, to the equalization of taxes and to many of the necessary operations of general and municipal governments, as well as of private individuals. But in this country where legislation usually follows, instead of leading, the expresssion of general public opinion, such works are likely to await the slow and gradual cultivation of the popular mind to a proper appreciation of their great utility.

CONGRESSIONAL LEGISLATION

In the meantime, it must be admitted that Congress has enacted a very liberal and wise law by which the Coast Survey is authorized to extend its triangulations over any State in which scientific surveys have been provided for by the State Legislature. Moreover the Superintendent of the Coast Survey evinces a disposition to construe this act with great liberality. It is understood that he will, where thorough topographical surveys are undertaken by State authority, cause the subsidiary triangulation to be carried to any reasonable degree of minuteness with the same refined accuracy which has characterized the work already done by the officers of the survey. Indeed, with their elaborate determination of local irregularities in the form of the earth, and their well organized corps of skilled observers and computers, they have an immense advantage, which could hardly be soon obtained by any new organization, for extending the triangulation over whole States and carrying it to the secondary and tertiary stages.

TRIANGULATION OF MASSACHUSETTS.

The State of Massachusetts is entitled to the credit of being the first of the United States to recognize the importance of having her territory carefully surveyed and to commence upon such a work. More than forty years ago, a triangulation was commenced which was completed in 1842. This triangulation will compare favorably with the Coast Survey work and with the other geodetic surveys of the world. But a surprising indifference to its value, or potential utility, seems to have prevailed, and up to the present time, no further use has been made of it than to adopt it for the basis of such State and county maps as have from time to time been published. These maps give only the horizontal locations of objects obtained from such imperfect surveys as could be paid for by the sale of maps, published entirely by private enterprise, no assistance being given by the State.

STATE SCIENTIFIC SURVEYS.

At the present time, the subject of scientific surveys is being agitated in the States of Massachusetts, Rhode Island, Connecticut and New York. The latter State appropriated $20,000 in 1876 for preliminary organization, to effect which it appointed a skilled director. The other States mentioned have organized commissions to investigate and report on the subject.

REFORM NEEDED IN LAND SURVEYING.

Before proceeding to describe the proposed combina- of surveying with geodesy, a brief consideration may be permitted of the urgent need of reform in the prevalent methods of land surveying and of writing descriptions in conveyances of land, based, as many of these descriptions necessarily are, upon imperfect surveys, and frequently upon no surveys at all. Lawyers and land surveyors are perhaps more familiar with the short-comings of these conveyances in failing properly to describe the property conveyed. A large share of litigation of the country arises from this cause. Indeed the laxity in this respect is something almost incredible. Scarcely one deed of conveyance in a hundred, will be found to contain such a description of the land conveyed as would fix its location with certainty, if the fences, walls or other inclosures should become obliterated, a contingency which is quite likely to arise.

CONFLAGRATION OF DETROIT.

An occurrence of this kind on a rather extensive scale took place in 1805, when the city of Detroit was devastated by fire, and so thoroughly destroyed, that it was found quite impossible to ascertain the former boundaries of estates. Their restoration was entrusted to the Governor of the State and a council of judges, who could find no better way out of the difficulty than by relaying out the city on an entirely new plan, dividing the lots among the former owners as equitably as possible.

Notwithstanding this experience, the lines of streets and lots in Detroit are now so uncertain that disputes and litigation in regard to them are of continual occurrence. The same is true in most of the cities and large towns of the United States, especially in surburban districts and growing villages where land is rapidly increasing in value.

FAULTY DESCRIPTIONS IN LAND CONVEYANCES.

If we examine the descriptions given in land conveyances, we shall find that they usually fail to fix either the location of the property by reference to permanent land marks, or even the position of its boundary lines relative to each other. Frequently the tract conveyed will be bounded in the deed by the several tracts adjoining, of which the only description given is to state the names of the supposed owners. In many deeds, all dimensions are omitted and only an indefinite approximation to the quantity of land conveyed is given, the statement being that it contains about so many acres, "be the same more or less." Where good permanent division fences, walls, hedges, ditches, streams shore lines, bound-stones, stakes, etc., mark the boundaries, and are properly described, such descriptions may answer the purpose so long as the boundaries remain unchanged, although such indefiniteness as to quantity would hardly be tolerated in the sale of other kinds of property.

OBLITERATION OF MONUMENTS.

But physical monuments are continually becoming obliterated even when well defined at first. It is said to be an old custom in some parts of the country, to take children once in every year to important boundary corners, where monuments have been erected, to the location and surroundings of which the careful attention of the children is directed. If on a subsequent visit, their memory is found to be at fault, it is refreshed and deepened by combining with it that of a sound flogging.

UNRELIABILITY OF SURVEYS.

Even where surveys have been made, they are in many cases so unreliable that the recollections of old residents in the vicinity, considerately stimulated, perhaps in their youth in the way described, are more reliable in determining the proper location of lost boundaries, than the retracing of old surveys. This is not surprising when the modes of surveying and the character of the instruments used are taken into consideration.

To be continued.

PUMPING ENGINES.*

BY JOHN BIRKINBINE, OF PHILADELPHIA.

In all metallurgical processes and mining operations, water is an element which receives attention from the management; and provision is required either for a means of supply, or for the disposal of accumulation. In many works the quantity of water to be furnished is sufficiently large to place the item of water supply of equal importance to the reception of material or disposition of product; and the means to be employed receive, or should receive, the most careful investigation.

There are exceptional cases where mines or quarries possess a natural drainage, but a large majority of the useful ores and the fuels delved from the earth are obtained from workings in which water accumulates and must be removed. Often the quantity to be disposed of is very great, and the distance to which it must be elevated amounts to hundreds of feet.

The magnitude of the work to be done, either in furnishing a supply for large metallurgical works or in draining extensive mines, demands the employment of powerful machinery, the economical operation of which is of great importance to the management, both as a pecuniary and practical consideration. It is therefore probable that a few notes on the general character of pumping engines may prove interesting to many of the members of the Institute. No attempt will be made in this paper to go into details of special machines, but the general features of the different classes will be briefly considered.

When a large amount of water is to be elevated to any considerable height, the prominent question to be considered is not "what will sufficiently powerful machinery cost?" but it is, "what will be cost per annum, or per ton of product, to drain the mine, or supply the works?" as the case may be.

To obtain this information it is necessary to be in possession of the following facts:

1. Fuel consumed to do a given amount of work.
2. Durability, and liability to derangement, breakage or repairs.
3. Cost of attendants, lubricants, etc.
4. Interest on first cost of machinery.

The items rank in importance in the order named.

The term "duty," as applied to pumping engines, indicating how many million pounds of water can be raised one foot by the consumption of one hundred pounds of fuel, is the generally accepted standard of comparison, and it is the true index of the merits of a machine when it is the result of long continued operation, considered in connection with the other items above specified.

A saving of a small amount of fuel each day is augmented into a large sum in a year, and represents the interest on a considerable outlay in construction.

Owing to the fact that in America it is mostly coal mines which require powerful pumping machinery, the "duty" of the apparatus has not been so jealously considered; for waste or culm is principally used for fuel, and the labor troubles have encouraged operators to employ cheap engines to a considerable extent, rather than economical ones of more expensive construction. But at these mines each ton consumed cost something to remove and handle, and therefore represents value.

An engine which is required to raise three hundred thousand (300,000) cubic feet (or two and a quarter million gallons) per day to a height of two hundred feet, would perform a work each day equivalent to raising 3,750,000,000 pounds one foot high. If this engine was capable of working with sufficient economy to give an average duty of sixty million foot-pounds (a duty within safe bounds), the daily consumption of coal would be 6,250 pounds, aggregating in one year 1,018 tons; if, however, it gave no higher duty than the average of American pumping engines, say twenty-five million foot-pounds, the daily consumption of coal would reach 15,000 pounds, aggregating in a year 2,444 tons, a difference in favor of the 60,000,000 engine of 1,426 tons. If this fuel cost but one dollar per ton, the saving would pay for at least two laborers' time, or if capitalized at seven per cent. would permit of an expenditure of $20,367 more for a 60,000,000 engine than for a 25,000,000 engine.

In mines where ores of the useful metals are extracted, the saving would be much greater, and in proportion to the cost of the fuel. If coal cost $4 at such a mine, the saving above would be quadrupled, and amount each year to $5,703, representing a capital invested of nearly $81,500—a sum amply sufficient to pay for a very elaborate pumping engine of more than double the power above cited.

For many years the "duty" of pumping engines has received prominence in European mining countries, and most of the reliable data which we now possess are the results of the operations of engines at foreign mines. The English operators deemed it so important that prizes were offered to engineers doing the most work with 100 pounds of coal. While this had the effect of showing what the engines would do, and improving the average duties, it also brought into existence the various plans of "doctoring" pumping engines to secure empirical and excessive duties by the exercise of sharp practices, thereby detracting from the reliability of some of the reports.

In America the records of duties are principally from water-works engines, but, unfortunately, many of them are the results of but a few hours running, under the most favorable circumstances, and with numerous allowances for imaginary contingencies, and do not indicate the daily operation of the engines. The duty of an engine is not to be considered the result of such a test, but it should be calculated from the water raised and coal consumed in a year or a series of years.

The liability to disarrangement of parts, breakage,

* A paper read before the American Institute of Mining Engineers at the New York meeting, February, 1877.

and consequent repairs exists, of course, in all machines to a greater or less extent; the ratio being practically in proportion to the number of moving parts, and not to the weights of the machines. Care in proportioning, and attention to details of construction, greatly reduce the possibilities of accident, but the more numerous the wearing parts, the greater are the probabilities of repairs, and, generally, the shorter the life of an engine.

A pumping engine may give a high "duty," and yet be so short lived as not to be an economical machine, for the numerous stoppages and expenditures required for repairs, or the rapid deterioration of the engine, often amounts to more than the saving in fuel.

The cost of attendance, while entering into the calculation of the economy of an engine, does not attain the importance often ascribed to it, for the maintenance of any large piece of machinery demands (and should receive) careful and constant attention from competent parties, and cheap engineers are among the most expensive features which can be introduced into any establishment. There is no just reason why a pumping engine should not receive as jealous and watchful care from skilled attendants as a blowing engine or rolling-mill engine, and yet some pumping machines are claimed as superior to others because "any boy can run them."

The amount of lubricants required for an engine are given a place in the comparison of different apparatus, not so much for the sum expended upon them (although this, in many instances, is no small outlay), as for an index of the durability of a machine, for generally the engines requiring excessive lubrication wear rapidly, and consequently are "short lived."

The interest upon the first cost of an engine, very properly, is considered in the estimate of its efficiency; but it is often accredited with more importance than is justly due it.

The consumption per day, or 100 lb. of coal, or of a quart of good lubricants, or a half-hour's work in the machine-shop for repairs, will, under ordinary circumstances, represent a greater amount per annum than the interest on a thousand dollars; therefore, where all these items are increased in any engine, its economy becomes doubtful, and any saving in its first cost is quickly absorbed by such daily expenditures.

These remarks apply to pumping engines without unnecessary ornamentation, for this should be a matter of separate consideration. Any good machine is worthy of a good workmanlike finish, and the addition of gilding, nickel plating, fancy turning or fresco painting is not to be estimated in the record of comparative economy. There are pumping engines now in use in this country which have cost, to put in place, over $300,000, yet I greatly doubt if there is in America a pumping engine worth, intrinsically, to-day $100,000.

A pumping engine is a compound machine, made up of a steam engine (or the essential parts of one) and a pump (or pumps) combined, connected and arranged in a great variety of forms.

The proper proportion and arrangement of the parts of an ordinary steam engine are now so well understood and generally agreed upon, that, as a motor for converting the steam generated in boilers into work, there seems to be but little room for further improvement, and the direction of invention is rather towards obtaining better results from boilers.

Among the acknowledged essential elements for obtaining economic operation in a steam engine are high piston speed and expansion; and a large majority of pump manufacturers consider slow piston speed as necessary to secure a high duty in pumping engines.

In dealing with such a ponderous and unyielding substance as water, there are many difficulties to be overcome in making a pump to work at a high piston speed, and it may be considered impossible to be able to operate a pump with the same velocity as is practicable with an engine using the lighter and more elastic form of water (steam) only.

The attainment of moderately high speed in pumping engines is, however, easily accomplished, and well-proportioned pumping engines of large capacity, which are provided with ample water-ways, and properly constructed water-cushioned valves have been (and are now) operated successfully against heavy pressures, at a speed of 250 feet per minute, without "thug," concussion, or injury to the permanency of the apparatus, and there is no doubt but that the speed can be still further increased.

Although the pump for raising water ante-dates the steam engine by some thousands of years, and is a more simple machine, yet, in the proportioning and constructive arrangement of parts, there appears to be no acknowledged standard.

The pumps are made to force or push the water, or simply to lift the water; there are double-acting piston pumps, plunger pumps, or bucket and plunger pumps. They are worked singly, or in pairs or more, so connected as to deliver the water at different intervals.

If we add to these the rotary and centrifugal pumping machines, and the numerous arrangements introduced to lift water by the condensation and force by direct pressure of steam, we have a variety whose name is Legion.

In the details of pumps of a similar class, there are as radical differences. Valves are made hinged or "flap," "poppet," "single-beat," "double-beat," or "treble-beat" (I prefer the expressions single, double, or treble seat as more expressive). They are made of leather, rubber, wood, brass, composition, or iron. In proportions they are constructed large enough to answer for each operation of charging or emptying the pumps, or they are divided up into a number of small valves.

In fact, there is in pumps no acknowledged and accepted general arrangement in which intelligent mechanics and builders approximate an agreement.

In combining the two essential parts of a pumping engine, the steam engine and the pump, there is as much difference of opinion and controversy as to the mode of connecting and the arrangement of the parts. Some are operated direct, the piston of the steam cylinder being connected directly with that of the pump; others have intervening gearing, beams, or bell-cranks.

A visit to the pumping works supplying our large cities will demonstrate the variety of design and arrangement adopted by various engineers; nor is this variety confined to the different cities, for many of them have, as a means of supply, engines differing materially; and the city which uses engines of similar design and construction is the exception rather than the rule.

The city of Philadelphia employs sixteen pumping engines in connection with its water supply, which represent ten distinct varieties. Providence employs four pumping engines, all of radically different types. Buffalo, Cleveland, Cincinnati, and other large municipalities, are similarly provided.

To secure the advantage of a high piston speed in the steam engine, and operate the pump at a slower velocity, numerous designs have been introduced. One of the largest engines of late construction, built to secure this result, is a vertical compound steam engine, transferring its power through gearing to horizontal pumps. The great objections to such a design are the multiplicity of parts, and the difficulty of procuring gearing which will operate without back-lash or play between the cogs.

Another engine, which is also of late construction, consists of a compound engine, each cylinder operating a pump by means of a rocking or oscillating beam, the connecting rods of the steam cylinder and of the pump being so disposed that the steam piston passes through double the stroke of the pump piston, but the same number of strokes are made in a given time, and the difficulty generally experienced is in the change of direction of the water, and the opening and closing of the valves, and not in the actual speed of the piston.

In an article published in one of our engineering journals the untenable position is taken that a multitude of small valves offer less resistance to the flow of water through them than one large valve; while practice demonstrates that large valves offer less resistance proportionately than a number of small ones aggregating an equal area; and if double-beat valves are employed of appropriate construction, they will close as soon as the current of water ceases to flow through them, without the addition of weights or springs or the return current of the water.

In using a number of small valves it is found necessary to load them, or to hold them down by springs, particularly if they are of rubber, to insure their closing; and even it is rarely found that they all close properly; an examination of a pump using such valves generally exhibits some of them chipped or held partly open, and a consequent loss resulting.

A valve should be complete in itself, and the necessity of the employment of extraneous forces to produce the proper operation of the valves is evidence of a defect of construction or a want of adaptability for the purpose for which it is employed.

In a recent test of a pumping engine an allowance is made for a pressure of six pounds per square inch for the operation of each set of valves; this seems excessive, for it reduces the suction power of the engine so that it cannot draw the water over eighteen feet.

A large valve is now in operation which offers a resistance of but 0.63 of a pound per square inch, or but one-tenth that just mentioned. This resistance is 382 per cent. of what is credited to the Lynn engine, and 85 per cent. of what, as stated, is required to lift the valves on the Lawrence engine.

The pumping engine which best meets the peculiarities of both steam and water is what is known as the Cornish engine, practically the Bolton and Watt single-acting engine.

The advantages of this class of engine is that the in-door or steam stroke of the cylinder can be made quickly, and the out-door or pumping stroke is made slowly, while the water is discharged as the weighted plunger settles; the steam passing from one end of the cylinder to the other, and forming an equilibrium during the interval between the steam and pumping stroke; and the connection with the condenser being made in the interval between the pumping and the steam stroke.

This form of engine is particularly useful in mines and shafts requiring long operating rods; and for general purposes, when a considerable volume of water is to be elevated, it may be considered as the most economical and durable type of pumping engine. This may be deemed a bold assertion in the face of published reports of some late tests; but I am convinced that a Cornish pumping engine properly proportioned, constructed and managed, will give, during its continued operation, equal if not superior economic results to any other form of pumping engine.

One great advantage of this class of engine is the variety of speeds at which it can be operated. I have seen a Bull Cornish engine capable of raising 1,250,000 gallons to a height of 230 feet, operating satisfactorily at speeds varying from 20 strokes per minute to one stroke in three minutes.

That class of direct-acting pumping engines without fly-wheels, the "tappet pump," is, on account of the press and judicious presentation to public notice, probably more popular than any other form at present. In their construction marked ingenuity has been employed, and where the work to be done is comparatively small, or the uses for which they are employed are of a temporary or supplementary character, they answer a very good purpose; but they do not prove to be either durable or economical in their operation.

In a recent defence of this class of engine, an attempt was made to demonstrate that a crank controlled by a fly-wheel and the motion of the piston or plunger of a pump, produce a constant damaging conflict of forces, which not only absorbs a large percentage of power, but also tends to destroy the machinery.

The motion of the piston of a pump, produced by a crank with a fly-wheel of sufficient momentum to maintain a uniform velocity, is from rest at the "dead-point," by accelerated velocity, to a full stroke at 90 degrees, and from that point, by constantly diminishing velocity, to the opposite dead point, where there is sufficient rest to permit of valves seating themselves, and the direction of the water changing, the return stroke being from the "dead point" by accelerated velocity to 90 degrees, and thence, by decreasing velocity, to rest again. These so-called conflicting forces only come into play when a high degree of expansion is attempted with a single steam cylinder directly connected to the pump; and hence one of the objections to the Cornish engine. To secure the full value of expansion it is necessary to use a fly-wheel, or other heavy moving part to absorb the excess of power at the early part of a stroke, and give out power at the latter part of the stroke. Steam entering the cylinder of a Cornish engine strikes a blow (so to speak) upon the massive portions of the engine (which are constructed to receive this blow), and gives to the piston a momentum which is accelerated while the steam follows it, and then retarded as the steam expands, until the pressure of steam and weight of the

moving parts are in equilibrium at the end of the stroke. Admitting, then, the conflict of forces, does not the value received by expansion more than neutralize any additional cost in the proportioning of an engine?

By using a compound engine and expanding from one cylinder to the other, and constructing the pumps in duplicate, a moderate degree of expansion is obtained with tappet pumps; but this duplication of parts is, in plain words, the construction and maintenance of an entire steam pumping engine in place of a simple and inexpensive fly-wheel, with practically no wear, or expenditure for maintenance.

Very superior engines, and those which rival the Cornish in economic duty, are constructed with compound steam cylinders, bucket and plunger pumps, beam and fly-wheel, the compound cylinders in connection with the fly-wheel permitting a high degree of expansion.

Special conditions may make one form of pumping engine more desirable than another, but under ordinary circumstances, where a large volume of water is to be lifted to a considerable elevation, the superiority of well proportioned and constructed pumping engines may be considered to rank as follows for economy:

1. Cornish, or single-acting engines.
2. Compound engines, with fly-wheel.
3. Condensing engines, with fly-wheel.
4. Compound engines, without fly-wheel, duplex pumps.
5. High pressure engines, with fly-wheels.
6. Condensing engines, without fly-wheel.
7. High pressure engines, without fly-wheel.
8. Rotary and centrifugal pumping engines.

It is hardly fair to place the rotary and centrifugal pumps among pumping engines requiring to be in constant service under heavy work, but they have been brought so prominently into notice that they deserve mention. The rotary engine and pump possess in theory so many apparent advantages that great ingenuity and much money have been expended in attempts to perfect a reliable apparatus.

One design proposed for mines demonstrated that the inventor had been so impressed with the rotary principle that he introduced obstructions in the delivery part of his pump, which, in connection with wings or blades on the revolving shaft, kept the water in a rotary motion regardless of the fact that all the power expending in rotating the water was entirely lost, so far as lifting it was concerned.

Another inventor constructs his delivery pipe of a series of inclined planes, changing in direction every few feet, under the impression that water will ascend in a zig-zag course with its increase of resistance more readily than in a solid vertical column.

This paper is, however, not intended to discuss particular machines, but only in a general way classes of pumping engines, and the above are introduced as instances of devotion to the rotary class. It is rather the principles of construction with which it is intended to deal, hence there is no reference of comparative duty tests. This I have reserved for future consideration, and shall be pleased to receive records of any pumping engines accessible to the members of the Institute.

In ascertaining the duty or actual commercial value of such an important machine as a large pumping engine, there need be no difficulty in arriving at an exact measure of comparative economy and merit, without resort to hypothesis or guessing at results. All the elements entering into the intelligent understanding of the subject are easily ascertained. They are

1. Fuel actually consumed, with oil, packing, etc.
2. Weight of water delivered × height lifted × friction.
3. Reliability and durability.
4. Attendance and repairs.
5. Comparative first cost.

These facts can all be obtained and the results readily worked out to the satisfaction of any one interested in the operation of pumping engines. In some of the records of empirical tests there seems, however, to have been so much high art and scientific ability displayed that even to those with moderate attainments in mechanical engineering the *modus operandi* of securing the result is a mystery.

It has been claimed that the indicator is the best means of determining the relative value of pumping engines, for it tells the tale of the inside workings of a pump or steam cylinder. Recognizing the value of indicator diagrams, I cannot conceive that they are as valuable in comparing various pumping engines as the record of the coal heap and the discharge weir. Comparison by indicator diagrams are likely to be unjust unless they are taken with the same or a similar instrument, located in like positions on the various engines, and given in connection with the speed and work performed by the different machines.

The contraction of water-ways, proportion and kind of valve also have a marked effect upon the appearance of cards taken from a pump cylinder.

While indicator diagrams are of great service to the engineer, and their comparison has done much to improve various motors, there are so many affecting causes to be considered that it is difficult to make satisfactory comparisons of the records of different parties. A candid comparison of the elements proposed in this paper will give a just precedence to good engines, and I am convinced will sustain the relative order of merit as given.

DISCUSSION.

The chairman said he was glad to hear this subject brought forward in a place and atmosphere where it could be, he trusted, discussed without passion or the bias of pending personal interest; and he took pleasure in recognizing the strictly professional tone of Mr. Birkinbine's paper, it being well known that that gentleman's business relations were such as to tempt him to a different style. With reference to the reported high duties of Cornish pumping engines, he begged to refer to an article in the *Engineering and Mining Journal* of March 5, 1877, where his views had been expressed. The great excellence of the Cornish engine as a mine-pump was, however, admitted.—*Engineering and Mining Journal.*

PERSONAL.

J. Francis LeBaron, C. E., of Boston, has been commissioned to make collections in Natural History and to carefully examine and study the aboriginal remains, etc., of Florida, for Harvard University, the Smithsonian Institute of Washington, the Essex Institute of Salem, and others, making Jacksonville his headquarters.

ON THE PROBABLE ERRORS OF LEVELING; WITH RULES FOR THE TREATMENT OF ACCUMULATED ERRORS.*

BY WILFRED AIRY, B. A., M. INST. C. E.

(Concluded from page 98.)

Mr. Adie observed that no reference had been made to the refraction of light. He believed that if there was an error in leveling in one direction compared with leveling in the other direction, the probable cause, in some degree at least, must be from the refraction of light. This was explained to some extent, by the fact that the tables showed that the Indian levels were, on on the whole, much more accurate than the English. Whether that was from the purer atmosphere, or not, he did not know, and the same indeed applied to the Swiss. In the transit of a star refraction did not matter, because it was equal on both sides; but it was not so in leveling, and probably this was the cause, in some degree, of the different results obtained in leveling in the different directions.

Major Courtney, R. E., observed, through the Secretary, that the method proposed by the Author, though certainly ingenious, and doubtless securing a high degree of accuracy, was, in his opinion, far too complicated and involved too great an amount of office work to be of much practical use. Besides, from an inspection of the Indian leveling results, it appeared that, owing to the strict precautions used to prevent any large differenc accumulating in the work of two observers, their results left little to be desired in point of accuracy, and this without all the laborious calculations of the proposed method. Their system of getting rid of cumulative errors in the field involved but little computation, and was far better for practical purposes. With respect to the English results being so inferior to the Swiss, he found that the latter, in order to get the best results, took the utmost pains, and used every instrumental refinement, even putting highly-trained officers on the work to make the observations. It was then only to be expected that their work should be superlatively good; on the other hand it must be far more expensive per mile. He thought this should be stated in fairness to the English work.

Mr. Airy, in reply, drew attention to two levels lent by the firm of Troughton and Simms. One was an ordinary dumpy level, the other "The Italian Y level," designed by Mr. Simms according to a plan well known on the Continent. The latter had all the proper movements for easy adjustment in collimation, and the level was not, as usual, attached to the telescope, where it was liable to knocks, but to the frame, where it was much more sheltered. Levels of that size were not used for the standard leveling of countries; they were far too insignificant for that work; but they were convenient for engineering purposes. It had been remarked that the degree of accuracy mentioned in the paper had little reference to ordinary engineering operations. That was perfectly true; but of course there was no reason why one should not search for greater accuracy than was ordinarily necessary, and for geodetical purposes—and the paper was more directed to geodetical purposes than engineering works—a high degree of accuracy was necessary. It had also been said that errors caused by the waving of the staves, and so on, were not of great consequence, because if an error was made going up hill it was cancelled in coming down; so that if the operations were completed at pretty near the same level from which they had been started no large final error would have crept in. But in leveling over several hundred miles, going up a height of several thousand feet, and down again, the top point was very likely to be a great deal in error. No doubt Mr. Bunt's leveling, which Mr. Barlow had referred to, was quite historical in its way. It certainly was found out by Mr. Bunt and Dr. Whewell for the first time, that if levels were made in one direction to a distant point and then back again, different results were obtained—in fact, that there was a kind of orientation in leveling—that in lev- from north to south a different result was got from that obtained by leveling from south to north. That had been amply verified by Colonel Walker in India who, in one of his reports, described the source of the error, which he believed to be the most significant of all causes of error, and said; "A good deal of uncertainty exists in reading the level, owing to its being usually placed above the telescope and nearly in the the same plane as the eye of the observer, who gets a side view of the bubble, which is never as satisfactory and sharply defined as the look-down view from above. The r m round the bubble, caused by the adhesion of the liquid to the sides of the tube, becomes so prominent that in certain lights its extremities may be taken for the ends of the bubble. When light falls obliquely on the instrument, the outer edge of the rim towards the light is more clearly defined than the inner, while at the opposite end of the bubble the inner edge is more clearly defined. Hence there is a tendency to bring the bubble too much towards the light, and give the reading an erroneous bias, which some observers might guard against more than others." That was how Colonel Walker explained the difference of the results obtained in going in one direction or another. With regard to the error arising from the effect of temperature on the length of the bubble, he did not think that it would be sensible with the best modern levels. In the Swiss leveling, and in the Indian leveling, the ends of the bubbles were always read. There was never any question of setting the bubble exactly true. It was set true within certain limits, and then the ends were carefully read and booked, and corrections applied for the amount it might be out of truth, so that there would little uncertainty arising from that source. Mr. Binnie remarked that there was an error due to the unequal illumination of the staves on going from east to west, or in any way in which the light fell very sharply. To reduce this short readings must be taken, so that the unilluminated could be read as clearly as the illuminated one. This would make the work a little slower. It was an error that came under the head of genuine errors of observation, and no doubt was included in the figures he had exhibited. Mr. Redman remarked that no doubt the reason why the English leveling showed badly as against the Indian and the Swiss was because it was executed in a hurry. He believed that was the case; but at any rate the English leveling was begun in 1844 when people

did not understand leveling so well as now. The care given to the leveling in India and Switzerland was extraordinary, but the English leveling was comparatively antiquated. With reference to what Sir John Hawkshaw had said, he should have considerable doubts of any results or calculations referring to the mean level of the sea around England as deduced from the English leveling. The leveling was not good enough to prove things of so much importance, and the levels required to be checked over and over again with superior instruments and care. He did not think that any sensible error could arise from the elliptical form of the earth. The weight of the staff, no doubt, would operate if the ground was soft; but in all standard operations much more care was used than to place the staff on soft ground. In India a peg was driven to every position of the staff, and so each peg became, as it were, a benchmark. The succeeding observer who checked the work invariably put his staff on the same pegs, and so there was absolutely a benchmark from reading to reading the whole distance, and if a mistake crept in it could be located immediately and rectified. The Australian leveling mentioned by Mr. Arthur Woods undoubtedly was very good, and was on a par with modern good leveling, as shown in the paper. With respect to Major Courtney's remarks, he would state that the closing error of an extensive system of levels, however carefully the work was done, was almost certain to be too great to be disregarded, and needed to be dealt with in a formal manner. There was no short cut to such adjustments, and it would be seen by a reference to their reports that the Swiss engineers devoted an immense amount of labor to the adjustment of extremely small errors.

TO MAKE STONE WALLS WATERPROOF.

A correspondent asks for a process which will make stone walls waterproof. What is known as Sylvester's method has been thoroughly tested, and so far as we know has proved effectual. It is said to have been applied to the walls of the gate-house of one of the New York reservoirs, and to have remained impervious to water under a head of thirty-six feet after a trial of six years and a half. The process is described as follows:

"Dissolve Castile soap in water, three-fourths of a pound to the gallon; dissolve one half pound of alum in four gallons of water; both to be completely dissolved before using.

"The walls should be clean and dry, and the temperature of the air not below 50° (F.) when the solutions are applied. First with a flat brush lay on the soap wash boiling hot, taking care not to form a froth on the brickwork. Let this remain twenty-four hours, to become dry and hard; then apply the alum wash, which may be at a temperature of 60° or 70° and allow it to remain twenty-four hours before repeating the soap wash. Repeat the washes alternately till the wall is impervious to water."

"Water-glass," which is a silicate of potash or soda, has also been used successfully for the same purpose. The following, which the *American Architect* translates from Ramee's "Architecture Pratique," is a description of the original Kuhlmann process of silicatization:—

"The solution of silicate of 35° density (by Beaume's hydrometer), as found in commerce, contains one-third its weight of dry silicate (of potash or soda). Diluting a solution of this density with one and one-half times its volume of water, we obtain the most suitable degree of concentration for application to stone. With these directions, any one can prepare a suitable solution.

"To dissolve the dry silicate, if it is procured in that form, is difficult, but it is made easier by using, instead of pure water, water in which a little silicate is already dissolved. Pulverize the lumps, and, adding the silicated water, boil the mixture, stirring constantly.

"The proportion of the salt above indicated, viz., one part to eighteen of water by volume, in the liquid ready for use, is not essential, but a stronger solution penetrates the stone less readily, and a weaker one requires more applications. The last coat may with advantage be slightly more concentrated than the others.

"For applying the silicate, the stone must be perfectly clean. In old buildings it must be scraped to a new surface; or, if this is impossible, brushed with a stiff brush, and a lye of caustic potash. No acid must be employed. The solution is applied to large surfaces with a syringe and rose, first making troughs of clay at the foot of the wall to collect the excess of liquid. For small surfaces it is applied with a soft, thick brush, to take up as much solution as possible at once. Care must be taken to protect the windows with cloths, as the silicate will make spots difficult to remove.

"After each application an interval should be left of several hours, or better, a day. In general, three applications on three successive days will be sufficient. Too much of the silicate will give the stone a disagreeable glazed look, which must be rectified by washing the stone immediately before the silicate is hardened by the air.

"The process may be applied at any season, excepting in freezing weather, but warm and dry weather is preferable. If the sun is very hot, cloths should be laid over, to prevent too rapid drying."—*Boston Journal of Chemistry.*

A NEW IRON RAILWAY TIE.

The past twenty-five years has witnessed the grand development of the railway systems of the world, and keeping pace with it, great and vital improvements have been made in rolling-stock, permanent structures, and all methods of management; but in the matter of permanent way, the practice of to-day is essentially that of twenty-five years ago, and a majority of railway accidents are traced to what appear to be its insuperable defects.

This statement needs qualifying to a certain extent. The road-bed has undoubtedly improved through more efficient ballasting and better drainage, the fished-joint, though leaving much to be desired, is generally adopted; and lastly, the Bessemer metal rail has largely supplanted the iron rail, not that a carefully made homogeneous iron rail is poorer, but simply because railway managers would not pay the price of such rails conscientiously made. So with the exception of methods and details, and possibly the adoption of the fished-joint, the improvement in permanent way has been practically *nil.*

Formerly there was some difference of opinion as to the relative merits of longitudinal sleepers, giving continuous support, and cross-ties; but of late years cross-ties, spaced two to two and a half feet, have been almost universally accepted as giving the necessary elasticity combined with the requisite facilities for repairs. Stone blocks have been employed and are still to a limited extent but the devices lately invented to overcome their destructive rigidity have not proven satisfactory. Various forms of metal ties, chiefly cast-iron, have been recommended, but owing to their great first cost as compared with that of the common wooden tie and the absence of many of its characteristic qualities, they have not been able to compete with it except in tropical countries, where the wooden tie is subject to rapid decay and often to quick destruction by insects, chiefly white ants; also in districts where the scarcity of timber practically prohibits its use.

In this country the wooden cross-ties, we believe, are universally in use, and as long as a good oak tie can be obtained for 75 cts. the adoption of metal may be considered as doubtful, although we are persuaded that but for the inertia of railway companies they would see in it not only a direct economy in money, as we shall presently show, but an additional insurance against accidents from overturning rails and spreading of tracks. Already the need of a substitute for wood is felt in our lines across the plains. The rapid depletion of our timber supplies is exciting grave apprehensions in the minds of the thoughtful. Soon some system of forest culture must be instituted or timber in many of its present uses will be abandoned. When it has been stated that the cost of replacing the railway ties of this country is over ten million dollars annually, the magnitude of this item alone and of any proposed saving becomes enormous.

The average life of a railroad tie is about seven years

Let us assume certain data and make a comparison in order to determine how much a railway company can afford to pay for one of metal. Assume that a metal tie will last twenty-one years or three times the life of a wooden tie. Omit the minor factors such as surfacing, replacing rotten ties, and other repairs, which will vary in each case. Any discrepancies which may result will favor the wooden tie.

Take the cost of the wooden tie at 75 cts. delivered, and the spikes at 10 cts., the tie to be replaced twice and the spikes to last the entire time of 21 years. Then compounding at 6 per ct. the amount approximately of

85 cts.	for 21 years	$2.89
75 "	" 14 years	1.09
75 "	" 7 years	1.13
		$5.71

This represents a capital compounded at 6 per cent. of $1.68 which is the price that can be paid for the assumed metal tie. Compounding the interest at 10 per cent. the capital that can be expended is $1.43.

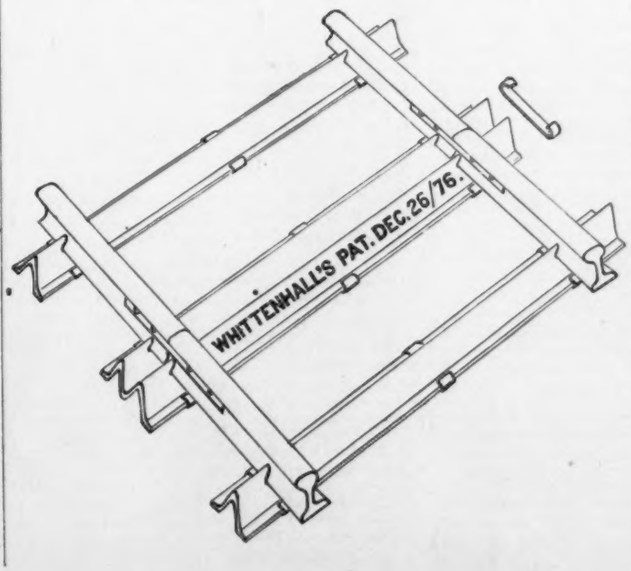
If we prefer to treat the problem in the ordinary manner, assuming the data as above and 1.12 cts. as the annual cost of keeping a tie and spikes in place, at 6 per cent., an invested capital of $1.87 would be required, and at 10 per cent., of $1.12, which sums at the assumed rates of interest might be expended on a metal tie.

If to this we add the fact that after the metal tie is worn out you have still a stock of iron which can be remanufactured, of course with some loss of material, and also, that every railroad company can turn its old rails and junk into ties for the cost of manufacture, the showing will appear exceedingly favorable to every railroad man.

Apparently conclusive experiments, recently made in England, show that steam injected into a reheating furnace, the iron being at a white heat, forms a skin, homogeneous with the iron, of black or magnetic oxide, which resists not only the corrosive effects of moisture, but even of the acids that ordinarily attack iron with avidity; subjected to some such process the life of an iron tie should be indefinitely prolonged.

The data assumed makes no pretensions to accuracy we being desirous of only relative results. We think a closer calculation by any railway engineer with complete data at hand will show that we have favored the wooden tie at many points. The assumption that a wooden tie can be bought 14 years hence for 75 cts. is probably far wide of the truth.

The above remarks have been suggested in part by an examination of the "*Whittenhall Patent Corrugated Metallic Railway Cross-Tie.*" This examination has convinced us that it possesses most, if not all, the essential requisites of a good railway tie, and at a cost sufficiently small to warrant its early introduction. Probably experience will show many advantageous improvements to be made in its construction, but we are persuaded that this or a similar structure will soon be a prime necessity.



The cut presented herewith illustrates the invention so well that a lengthy description seems unnecessary. The single tie has 8" earth bearing, the base of the equilateral triangle being 5", and the flanges 1½' each. The double or joint tie has 12" earth bearing, the flanges being 1" each. By the use of clamps on the bottom of the tie, it can be made much lighter; while by making the middle clamp tight and the outer ones somewhat longer sufficient play may be given to preserve the elasticity due to the shape. The earth when tamped fills the corrugations and is in a measure kept dry and hard. The rail seats are cut by a double horizontal punch of simple construction. The ties can be manufactured from old

rails, scrap or new iron, as the case may be, by simply piling and rolling into shape, and at a cost not exceeding that of any commercial iron, and probably less owing to the material allowable in their construction. When useless from rust they can be re-rolled as cheaply as any old iron.

Among the advantages claimed for this tie over those of wood are—there are no spikes used; there is no danger of the track spreading or rails overturning; it saves a larger amount of the section work after the track is laid, as there are no spikes to watch or rotten ties to look after; it lasts much longer, and it is cheaper in a term of years on most roads of this country, and cheaper in first cost at the present time on railways west of the Missouri river. Moreover, while a money saver, it is a great insurance to life and property. Neither is it liable to loss from fire, flood or theft. The elasticity of the tie means less wear and tear of rolling stock and rails. On account of less bulk and weight as compared with wooden ties, allowing cars to be loaded to their full capacity, they can be freighted long distances much cheaper. It will be seen that we have a sort of universal panacea for most of the evils of permanent way.

The inventor claims that with the use of a derrick car and eight men one mile of either old or new track can be laid per day, ready for tamping. When the tie is in place a stroke of the hammer clamps it to the rail. To remove a rail it is necessary to disconnect the fish-plates, shove the section aside, and after loosening the clamps draw it out. A tie may be removed when worn out by breaking the clamps. The results of a few calculations which we have made may be of interest as bearing out some of the foregoing statements.

The tie is assumed 66" in length and of ¼" metal. The weight of a single tie would be 60 lbs., and of a double or joint tie, 101 lbs., and costing at $42 per ton respectively $1.12 and $1.90 a piece; or with rails of the usual length, an average of $1.18. Taken in connection with previous figures this gives a practical saving margin.

The area of the section is 3.27 sq. in., and its moment of inertia about its neutral axis 4.285, assuming a tensile strength of 48,000 lbs.; the moment of resistance to bending is 70,000 approximately. This theoretical result is not to be depended upon as exact in the absence of experiment on this form of cross-section, but the true value cannot differ greatly. The heaviest freight locomotives (six wheels) have weights of 12,000 lbs. on each driver, and with the tie well tamped would produce a strain of approximately 12,000 lbs. at the middle of the tie. If thought desirable this strain could be lessened by lengthening the tie; thus a 7' tie would give a middle strain of approximately 7,000 lbs. If the tie were fixed at centre, as a cantilever, the strain would be only 28,000 lbs. The shearing strain approximately 3,500 lbs. per sq. in.; the crushing strain at rail seats, 6,000 lbs. per sq. in., and the factor on buckling of the sides not less than eight.

The detail calculations show that the material can be so distributed as to give greater strength with at least 25 per cent. less metal. Such shapes would be expedient should experience demonstrate the possibility of guarding against corrosion. They could be made by the aid of cam-rollers.

The invention we understand is soon to be tested by the laying of a considerable length of track on the main line and in the freight yards of one of our western roads. We hope to be able to speak favorably of the results.

ANNUAL MEETING OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS.

(From our Special Correspondent.)

NEW ORLEANS, *April 24, 1877.*

The main body of the American Society of Civil Engineers arrived in New Orleans last evening, having come from the east or west to Louisville, the place of rendezvous, and thence by special train via Mobile, where the whole party, sixty-six in number, stopped for several hours to visit special points about that city. Previously there had arrived at New Orleans various straggling parties, making the whole number registered at the St. Charles hotel last evening, nearly one hundred.

At 10 A. M. to-day the Society and its guests met at the Chamber of Commerce Building. The retiring president, Mr. Greene, being absent, the duty fell to Col. W. Milnor Roberts of delivering the opening address. In it he referred to the object of the meeting in this city, mentioned points of historic and general interest, in which the Father of Waters came in for the usual apostrophe, referred to the works now in progress at its mouth, etc. The growth of the Society from 50 in 1867 to 580 in 1876, and its accompanying results were duly treated. Altogether his address was quite happy and awakened repeated cheers.

After the reading of the address, that venerable student of hydraulics, Prof. Forshey, was elected Chairman which he gracefully accepted in his eccentric way by a neat little speech. Mr Bogart was elected Secretary pro. tem. and Mr. Emery his associate.

The Secretary read a communication from the city Fathers giving the freedom of the city to the members of the Society and guests, and a committee was appointed to confer with them on arrangements for visiting objects of interest in the city and vicinity.

On calling the roll the following members were found present:

James Archibald, Washington, D. C.
Wm. H. H. Benyaurd, Capt. of Eng's, Memphis, Tenn.
John Bogart, Eng. Dpt. Public Parks, N. Y.
Adolphus Bonzano, Pœnixville, Pa.
Louis G. F. Bouscaren, Ch. Eng. C. S. R. R., Cincinnati, Ohio.
Elmir L. Corthell, Asst. Eng. Jetty Co., N. O.
David W. Cunningham, Asst. Eng. Boston Water Wks.
Oliver E. Cushing, Lowell, Mass.
F. De Funiak, L. & N. R. R., Louisville, Ky.
J. E. Earley, C. S. R. R., Cincinnati, Ohio.
Henry Earnshaw, Cincinnati.
Ellis S. Clarence, Boston, Mass.
Chas. E. Emery, New York City.
F. U. Farquhar, Maj. of Engs. U. S. A.
Albert Fink, Louisville, Ky.
J. F. Flagg, Meadville, Pa.
C. G. Forshey, New Orleans, La.
W. F. Foster, Nashville, Tenn.
J. B. Francis, Lowell, Mass.
Edward D. Frost, New Orleans, La.
J. P. Gould, Roundout, N. Y.
John Griffin, Phœnixville, Pa.
Clemens Herschell, Boston, Mass.
Max Hjortsberg, Chicago. Ill.
C. W. Howell, Capt. of Engs. N. O., La.
W. E. Kelley, New Brunswick, N. J.
E. C. Lewis, Nashville, Tenn.
T. D. Lovett, Cincinnati, Ohio.
John MacLeod, Louisville, Ky.
Chas. MacRitchie, Milwaukee, Wis.
Niles Meriwether, McComb City, Miss.
Robt. Moore, St. Louis, Mo.
E. S. Philbrick, Boston, Mass.
F. C. Prindle, Philadelphia, Pa.
A. L. Rives, Mobile, Ala.
W. M. Roberts, New York.
Wm. Rotch, Fall River, Mass.
Wm. H. Searles, Rochester, N. Y.
W. Sooy Smith, Maywood, Ill.
C. H. Strong, Cleveland, Ohio.
E. W. Vaughan, Louisville, Ky.
C. D. Ward, Jersey City, N. J.
H. M. Wightman, Boston, Mass.
W. H. Wiley, New York.
W. E. Worthen, New York.
Wm. H. Newton.
E. N. Doane, Meadville, Pa.
D. E. MacComb, Washington, D. C.

ASSOCIATES.

Arthur Beardsley, Swarthmore, Pa.
C. B. Brush, Hoboken, N. J.
E. C. Davis, Northampton, Mass.
Robt. Fletcher, Hanover, N. H.
C. M. Harris, New York.
Authur Spielman, Hoboken, N. J.

JUNIORS.

J. B. Davis, Ann Arbor, Mich.
A. R. Hill, West Haven, Conn.
Alfred Noble, Detroit, Mich.
F. O. Whitney, Boston, Mass.
Samuel Whinery, Chattanooga, Tenn.
Sanford Horton, New York.
F. Brooks, Boston, Mass.

MISCELLANEOUS.

Fred W. Merz, (fellow) Louisville, Ky.
Chas. R. Flint, (fellow)
C. F. Allen, (guest) Boston Society.
E. Powell, " Chicago, Ill.
Geo. C. Morgan (guest) Engineer's Club of N. W., Chicago, Ill.
J. H. Gardner, (guest) New Orleans.
J. a d' Hemecourt, (guest) City Surveyor, N. O.
P. M. Moore, St. Louis Club.
Benj. H. Harrod, (guest) New Orleans.
Thos. S. Hardee, " New Orleans.
H. P. Darock " Detroit, Mich.
C. A. Henry, " New Haven, Conn.
R. L. Engle " Chattanooga, Tenn.
Prof. W. Watson, " Boston.
Arthur May, " N. Y. City.
L. E. Cooley " Eng'rs Club of the N. W., Evanston, Ill.
M. T. Endicott, (visitor) New London, Conn,
Maj. C. H. Boyd, (guest) U. S. Coast Survey, N. O.
Maj. A. J. Wrotnowski, (guest) New Orleans.
J. A. Hayward, (guest) New Orleans.

Many others are expected which will extend the above list and make this one of the best meetings ever held by the Society.

After the roll had been called and visitors' names enrolled the Secretary read the programme, for the most part as given in the NEWS of last week. The convention dinner is to be held at Lake Ponchartrain on Thursday. The business meeting was fixed for 3 P. M. of Wednesday. In the meantime Lieut. Davis stated to the Society the fact that Capt. Eads was kept away from this meeting on account of sickness and expressed the hope that he might be able to be present before the Society left the city.

The first paper discussed was that by Chas. MacDonald, on the Ashtabula Bridge. Remarks were offered by Robt. Briggs, Theo. Cooper, Chas. Newton, Mr. Searles, C. Shaler Smith, and others, the general conclusion being that astonishing incompetence was displayed in its design,—and as one writer remarked, the only fact of value to be drawn from the catastrophe was that a bridge with a factor of safety of one and one-tenth had stood eleven years,—and that the inspection was very inefficient. The general remedy proposed was official inspection by men entirely separate from corporate interest, either appointed by the general or State government, and a recommendation that a committee of four from the Society be appointed to draft a law, and that individual members interest themselves in procuring its passage in the various States, so as to secure practical uniformity in its workings.

At this point an invitation from Capt. Cowden was read inviting members to visit the Barataria Ship Canal Route to the Gulf, and that a small steamer would be ready to take such as wished to go on May 1st, returning on the 2d. After thanking Capt. Cowden for his invitation the Convention took a recess for half an hour to meet again at 1:30, P. M.

After the meeting re-commenced, the Society listened to a paper by Mr. Chas. Emery on the Relative Quantity of Materials in Girders of different types.

The paper was highly analytical and critical—treating of the relative depth, angle of braces, ties, etc., by which a girder could be constructed of a minimum weight or cost, the equation of values being of the 1st degree only, and allowing of the introduction of factors representing wood and stone, in fact all that enters into bridge structures. The paper was evidently regarded as of high analytical value.

A Discussion took place on special points by Gen. Smith, Mr. Bouscaren, Mr. Griffin, Mr. Philbrick, and others.

A paper was then presented by Maj. Howell on the Improvement of Galveston Harbor, in which the Gabion method of making piers or walls for directing the current and consequent scour was described. This work has been previously described in the columns of the NEWS, and it is not necessary to notice it here.

A paper was presented by the Secretary for Gen. J. G. Ellis on the Flow of Water in Rivers, in which some late European discussions and formulæ were treated analytically. The paper is one of great value to the student of hydraulic engineering. Some very interesting remarks on the flow of water in the western levels

of the Erie Canal were made by Mr. Searles; and the errors in leveling of the 136 miles discussed. The remarks will undoubtedly be published, and we defer further remarks until such time.

Prof. Forshey spoke of Humphrey's and Abbott's formula in regard to the flow of water in the Mississippi, and of the necessity of further investigation into the flow of water in large rivers.

Mr. Corthell had not prepared a formal paper, but ofiered many interesting remarks on the works at South Pass as being on the general problem of river hydraulics. The first part of his remarks have already been furnished by the article in the NEWS of last week. Mr. Corthell was exceedingly frank in his remarks, confessing that they had been in a measure over-confident, but they were learning every day. The problem was by no means solved. Many things that they had tried had failed without apparent reason, and quite different expedients had to be adopted. The results of the work during and since the March rise had been very gratifying, and was very encouraging, and the project is now in a fair way to success. He then explained the works now executed, giving statistics and facts as to their general utility, which, for the most part have been published in these columns.

After some minor remarks, the Society adjourned at 4 P. M. until 7:30 P. M.

CONTRACTORS' INTELLIGENCE.

One of Alger's friction excavators, in use by Farwell, Sage & Co., Contractors, at Long Island City, N. Y., excavated 217,000 cubic yards of earth last year.

Mr. John G. Nepps, of Lebanon, Ohio, was recently awarded the contract to build all the bridges on the narrow gauge railroad near Cincinnati, Ohio. The contract will occupy nearly a year to complete.

The contract for furnishing and laying pipes and gates was awarded to Delos A. Chappell, for $192,246-50. The gates on the Chapman pattern. All hydrant bids were rejected.

The Water Committee of Allegheny, Penn., lately awarded the following contracts: Water pipes and sleeves to John N. Smith at from $28 to $32.25 per ton for pipes, according to sizes, and $55 per ton for sleeves. Miscellaneous castings to Thomas Carlin at 1 6-9 cents per pound. Fire plug boxes, stop cock boxes, washout boxes, at $1.50, $2, $3.50 and $5 per box.

The plan submitted to the Keystone Bridge Co. for the proposed bridge to carry the tracks of the New York, New Haven & Hartford Railroad over Bridge street in Springfield, Mass., has been adopted, and the contract for furnishing the ironwork awarded to the Keystone Co. The company has also about completed a pivot bridge 186 feet long for the old Colony Railroad at Somerset, Mass.

The Hon. Mr. Chauveau, President of the Harbor Commission, and Jos. Sheyhan, M. P. P., arrived back from Ottawa, on the 16th inst., and reported a satisfactory and gratifying result to their mission relating to the extra sum required to fully carry out the proposed harbor works at Quebec. They entered into arrangements with the Government on the subject which will admit of the contract immediately, and the inception of the undertaking at an early date.

The contract for the grading Superstructure and Ironing of the Waynesville, Port William and Jefferson Narrow Gauge R. R. was let to Geo. Pots & Co., of New York at $7050 per mile to be completed Jan. 1st, 1878. This line of 26 miles by its connections with the Dayton & South Eastern, and the Springfield, Pomroy & Jackson Narrow Gauges at Washington its eastern terminus and the Miami Valley at Waynesville, its western terminus gives a direct Narrow Gauge line from Cincinnati to the Jackson county Coalfields.

We are favored with the following information from Pawtucket, R. I., in relation to the Water Works Contracts:

The contract for Pumping Engine was awarded to the Corliss Steam Engine Co., Geo. H. Corliss, Treasurer. The engine is to be capable of delivering three million gallons of water in twenty-four hours into a reservoir 240 feet above the water in the pump wells or under an equivalent pressure. The duty guaranteed is 80 millions in a trial of two weeks running ten hours a day, new fires to be made each day and all wood used in kindling to be reckoned on the basis of 100 lbs. wood to 45 lbs. coal, no allowances to be made for ashes and clinkers, and 100 millions duty in a 24 hours trial conducted in the usual manner of conducting duty tests. The price of the engine, pumps and boiler complete is $23,900.

The contract for building No. 1 Dam on the Sudbury river for the Boston Water Works was awarded to Messrs. Beckwith & Quackenbush of Herkimer and Mohawk, N. Y. The following are the quantities of work with the prices bid;

12000 cu. yds. of earth excavation, 40 cts. per cu. yd., 900 cu. yds. of soil dressing, 30 cts. per cu. yd.; 350 cu. yds. broken stones, placed, $3.00 per cu. yd.; 100 cu. yds. cement concrete, $5.00 per cu. yd.; 60 cu. yds. brick masonry, $15.00 per cu. yd.; 250 cu. yds. riprapping, $3.00 per cu. yd.; 800 cu. yds. dry rubble stone paving, placed, $3.00 per cu. yd.; 1900 cu. yds. rubble stone masonry in mortar, $6.00 per cu. yd.; 30 cu. yds. split stone coping, $15.00 per cu. yd.; 20 cu. yds. floor paving, $20.00 per cu. yd.; 1250 cu. yds. cut dimension stone masonry in mortar, $18.80 per cu yd.; 2800 sq. ft. face dressing of six cut work, 25 cts. per sq. ft.; 8500 sq. ft. face dressing of pointed work, 15 cts. per sq. ft.; 3 M ft. B M spruce lumber placed, $3 .00 per M. Total amount of tender $48,485.00.

The bids for the superstructure of the bridge over the Tennessee River six miles north of Chattanooga, Tenn, on the Cincinnati Southern road, were opened by the trustees March 2d. The bridge, the masonry for which is already completed, is to be an iron truss bridge of eight spans, one draw-span, 280 feet; one channel span, 256½ feet; two shore spans, 208¾ feet each, and four other spans, 207½ feet each, or 1,784 feet in all. There were eight bids, as follows: Phœnixville Bridge Works, Clarke, Reeves & Co., $:17,355,90; Louisville Bridge & Iron Co., $132,744.00; Claflin & Sheldon, Cleveland, O., $134,661.00; Detroit Bridge Co., $156,-000.00; Keystone Bridge Works Pittsburgh, $156,-026.05; Baltimore Bridge Co., $157,202.50; Keystone Bridge Works (second bid), $159,102.10; American Bridge Co., Chicago, $184,057.00. The contract was awarded to the lowest bidders, Clarke, Reeves & Co. A press dispatch from Cincinnati says: Clarke, Reeves & Co., of Philadelphia, declining to sign the contract for the Tennessee river bridge on the Cincinnati Southern railroad, the contract was conditionally awarded to the Louisville Bridge and Iron Co.

Editor ENGINEERING NEWS.

SIR.—Proposals, twenty-seven in number, were opened on the 11th inst. for the improvement of Tiber Creek Valley, D. C., for which an appropriation was made by Congress last session. The work was divided into three parts:—Improving K st. N. between 1st and 3d sts. E.; filling different streets, and sewerage. The approximate estimate of quantities for the improvement of K st. was as follows: 19,122 cu. yds. earth excavation including a haul of 200 feet; hauling earth per cu. yd. per 100 feet over 200 feet; replacing 1771 lin. ft. 12-inch flag, 2375 lin. ft. 16-inch flag, 2087 lin. ft. 5 x 20 inch bluestone curb, 2525 sq. yds. brick sidewalk, 1420 sq. yds. cobble stone paving, and 4624 sq. yds. graveled roadway.

Highest bid for excavation, J. Danaher, at 40 cts. per cu. yd.; lowest, O. O'Hare, at 10 cts. per cu. yd.; highest bid for hauling, D. L. Roach, at 1⅞ cts. per sq. yd. per 100 ft.; lowest, T. Joyce, at ⅛ ct. per cu. yd. per 100 ft.; highest bid for replacing material, J. Danaher, $4,300.00; lowest, O. O'Hare, $1,796.00. The contract was awarded to P. Brennan at eleven (11) cents per cu. yd. for excavation, one-fourth (¼) cent per cu. yd per 100 ft. for hauling, and $1,800.00 for replacing material. Filling different streets, the contractor to furnish the earth, which is to be measured in embankment, and without reference to shrinkage or swelling. Total amount of embankment, 41,950 cu. yds.; highest bid for same, T. Kirby, at 33 cts. per cu. yd.; lowest, C. H. Eslin & Co., at 15 cts. per cu. yd. The contract was awarded to T. Joyce, at 17 cts. per cu. yd. The sewerage consists of 572 lin. ft. of 36-inch two ring circular brick sewer, 488 lin. ft. of 24-inch two ring circular brick sewer, 906 lin. ft. of 18-inch pipe sewer, and 54 lin. ft. of 15-inch pipe sewer, all with lateral connections, man-holes, etc., complete as per plan. Highest bid for 36-inch sewer, D. Looney, at $4.00 per lin. ft.; lowest. H. Himber, at $1.81 per lin. ft.; average, $2.80 per lin. ft.; highest bid for 24-inch sewer, D. Looney, at $3.50 per lin. ft.; lowest, D. McNamara, at $1.64¾ per lin. ft.; average, $2.39 per lin. ft.; highest bid for 18-inch sewer, C. H. Eslin & Co., at $3.00 per lin ft.; lowest, S. Cook, at $1.10 per lin. ft.; average, $1.90 per lin. ft.; highest bid for 15-inch sewer, C. H. Eslin & Co., at $3.00 per lin. ft.; lowest, S. Cook, at $1.00: average, $1.53. The contract was awarded to H. Himber, for $1.81 per lin. ft. for 36-inch sewer, $1.72 per lin. ft. for 24-inch sewer, $1.77 per lin. ft. for 18-inch sewer, and $1.54 per lin. ft. for 15-inch sewer. W. J.

LAKE SHORE AND MICHIGAN SOUTHERN RAILROAD.

In speed, directness and safety, there is no railroad which surpasses the Lake Shore & Michigan Southern, and the traveler who values his time, his life and his comfort, will go by that company's route. From the care bestowed upon the track, the solidity of the work, the scientific grading, the class of rolling stock, the certainty of trains agreeing with the established timetables, the almost fastidious choice of none but the best of officers, the stringent rules as to the sobriety of conductors, engineers and all employees, and the superintendence of none but qualified men, the Lake Shore & Michigan Southern have been enabled to get an unequalled safety of travel. There is no line in America more worthy of public patronage. In Chicago the business of the road is in the hands of F. E. Moore, Esq., the General Passenger Agent at this point, and he is doubtless proud of having the superintendence of a line so thoroughly adapted to the wants of the traveling public.

Chillicothe, O., has definitely concluded upon erecting Water Works. The clerk has been instructed to advertise for proposals.

The Urbana, O. water works capital stock $100 000 in shares of $100 each have been incorporated by Henry Fox and others.

The Kentucky River Bridge on the Cincinnati Southern Railway, described on page 37 of our current volume has just been tested.

The work is being pushed on the Montreal, Portland & Boston Railway. It will be opened in June, and will form another through line from Montreal to Boston.

The monopoly of the use of the entire water power of Niagara Falls upon the American side of the river, with canal, etc., is to be sold at auction on May 1.

Another index of the nearness of good times comes from Lynn, Mass., where the shoe manufacturers are running on overtime. The business is one-third better than it was one year ago.

The chief of engineers reports in favor of expending over $1,000,000 of river and harbor appropriation, inciuding $25,000 for Hudson river, $14,000 for Burlington, Vt., $25,000 for Erie harbor and $20,000 for Oswego harbor.

Brown & Co., of the Wayne Iron and Steel Works, Pittsburgh, have recently receivedi nquiries from London and Berlin for the prices of their "U. S." iron plates. These inquiries are the result of the exhibition of this brand of iron at the Centennial Exhibition.

The survey for the branch road connecting Canton with the Massillon & Coshocton R. R., Ohio, by way of Navarre, and terminating at Justus, was completed lately, and a profile of the route is being made out by Mr. Cock, the engineer employed by the gentlemen who have the matter in hand. Mr. Cock pronounces the route much more desirable than he expected to find it.

Capt. Berthoud, says the Cheyenne *Leader*, has completed the survey of the extension of the Colorado Central from Longmont, Colo., to Cheyenne. Work will be begun at once and pushed to completion. The distance is less than 75 miles, the grade easy, and the road can be built at small cost. The road will pass through as good country as there is in the west for the first 50 miles from Longmont to Box Elder.

The Grand Trunk Railway Directorate, of Canada, proposes to introduce steel cars in which to carry grain. They are to be shorter than the present cars and as much stronger as steel is than wood, which will permit of the grain being loaded higher than at present. The new cars are to weigh six tons instead of ten tons as now, and carry eighteen tons instead of ten. Cars of the new model are being experimented with.

Several New York, City railroad officials visited Philadelphia lately for the purpose of examining the new steam street cars on the Market street road. They were received by President John S. Morton of the company, and Mr. Louis Ransom, of Troy, New York, patentee of one of the cars. After a thorough examination of the cars they agreed to prepare memorials to be submitted to the Legislature of New York asking the privilege of experimenting with them in New York city. The delegation included Messrs. Philips, of the Third Avenue Line; Peters and Fields, of the Sixth Avenue Company; Mr. Sullivan, of Brooklyn, and others.

Much success has attended the adoption of steam for moving street cars in Paris. Along the grandest boulevard in the city, and winding through some of its busiest streets, turning sharp angles and climbing and descending perceptible grades, the Merriweather engines draw crowded cars from Arc de Triomphe to the Bastile, a distance of seven miles, at a speed of eight miles an hour, and nobody is hurt, and even the horses see it pass with contemptuous disregard. The engine is noisless and smokeless. It has proved to be far more economical than horse power, and a large additional number have been ordered.

The report of the committee of experts on the engines of the Chicago West Side pumping works has been handed to the Mayor. The engines have exceeded their claims. They can raise 15,000,000 United States gallons of water in 24 hours, elevate the volume 155 feet, and develop a duty of 90,000,000 pounds of water raised one foot with 100 pounds of ordinary anthracite. The failure of the first test was declared due to the following facts: the coal was poor; the boiler was partly filled with deposit, resorting to the artificial draft of a steam jet. The engines acting independent of supplying the city, the supply was more uniform.

The Toledo Harbor Work's contract calls for the improvement of the natural channel through Maumee Bay, by widening it to not less than 250 feet on top and 200 feet on the bottom; the channel to be dredged so that there will be fifteen feet of water there at the lowest stage. In order to accomplish this end, 50,000 cubic feet of earth will be excavated, and the work is to progress at the rate of 400 cubic yards per day, until it is completed. This will make the channel from the lake to the docks one that will allow the largest vessels to enter safely, and will be wide enough to allow tows to pass each other, even at the elbows.—a feat that has heretofore been next to impossible. The work will be pushed forward rapidly to completion, and then Toledo will have a really first-class harbor. Messrs. William Richardson & Co., of Toledo, have secured the contract.

ARCHES;

CONSIDERED GRAPHICALLY.

(*Continued from page 88.*)

50. As stated in § 46, the curves of equilibrium for a single load at successive points on half of the arch are shown in Fig. 10, and the other side would give a symmetrical figure. The ordinates $y-z$ cannot, of course, be scaled as closely as they can be computed. By calculating a set of values for M, as above, for a load on each point in succession, we can make a table which shall by inspection give the bending moments at all points of division for a load at any one; and, consequently, by adding the numerical factors, we can find the bending moment of any combination of loads, of any magnitudes, and can see what positions of the loads will cause the maxima positive and negative bending moments.

Such a table has been prepared, the span being divided into twenty parts, enough for the generality of cases. As a load on either side of the middle gives the same set of values in a reverse order, it is necessary to calculate but one half of the table. As many decimals may be taken as will give sufficiently accurate results.

PARABOLIC ARCH, HINGED AT ENDS. TABLE FOR M. $M = m\,c\,W$. VALUES OF m.

By the use of logarithms the labor of preparing another table for a different number of divisions is very little.

Each column belongs to the point of division whose number stands at its top, the numbers commencing at the left abutment. Each horizontal line contains the factor for bending moment at each point of division for a load W on the point marked at the beginning of the line. The values of H are placed, for convenience, in the last column.

51. As it was proved, in § 34, that the parabola is the curve of equilibrium for a load distributed uniformly horizontally, when we place simultaneously on each one of the nineteen points a load W, this rib ought to be very nearly in equilibrium. By footing up the vertical columns we shall get no result which differs from zero by more than about .01 c W. The values of M calculated in § 49 will be found in alternate columns in lines 6 and 14; for we then supposed only ten divisions. This table will be referred to again.

52. In the solution of any particular example, it will often happen that the points at which the weight will be concentrated will not coincide with the points of division which we have taken. It will then be necessary to determine new values of y_0 and H, which may be done by the original formulæ or by interpolation. A new table of M may be calculated, values may be interpolated in the one given here, or, if preferred, from the value of H and the vertical components of the reactions we may draw a curve of equilibrium for any combination of loads. The table here given, if not directly applicable, subserves two purposes, one to show how a similar table can be made, and the other to indicate by inspection what arrangement of loads on any arch will produce the maxima stresses.

If the successive values of any quantity increase at a tolerably uniform rate, any intermediate value between two given ones may be put in by simple proportion. Otherwise we may use the formula for interpolation—

$$\text{Desired quantity} = a + f\left[\mathrm{D}_1 - \tfrac{1}{2}(1-f)\,\mathrm{D}_2\right]$$

in which a denotes the first given quantity, f the fraction of a division from a to the desired quantity, and D_1 and D_2 the *first* and *second differences*. To illustrate, take the values of H in § 46. If we place these in a column as below, find the amount of *increase* from quantity to quantity, and then subtract these differences from one another, marking each + if it is an increment, and *vice versa*, we obtain the columns of first and second differences as marked. Now suppose that we wish to determine a value of H at $b = .5\,c$; a will be .3176, $f = \frac{1}{2}$, $\mathrm{D}_1 = -.0856$, and D_2, for an average value between .0312 and .0238, $= -.0275$. If we substitute in the formula it then becomes

b.	H.	D_1.	D_2.
0	.3906		
		−.0186	
.2c	.3720		−.0358
		−.0544	
.4c	.3176		−.0312
		−.0856	
.6c	.2320		−.0238
		−.1094	
.8c	1226		

$$\text{H (for } .5c) = .3176 + \tfrac{1}{2}\left[-.0856 - \tfrac{1}{2}\cdot\tfrac{1}{2}\,(-.0275)\right]$$
$$= .3176 + \tfrac{1}{2}\,(-.0856 + .0069) = .2783\,.$$

This value will be seen to agree with the one given in the large table, found by the formula (12.) § 46. The factor for y_0, at ⅓ of the interval between .4 c and .6 c, would, in the same way, be

$$1.3223 + \tfrac{1}{3}\left[.0570 - \tfrac{1}{2}\cdot\tfrac{2}{3}\,(.0283)\right] = 1.3382.$$

Careful heed must be paid to the signs.

53. Having carried the investigation thus far, it may help to fix the ideas to draw a curve of equilibrium for some combination of weights. We shall take but a few loads, in order to have the diagram clear, but the reader may vary the example by taking other amounts in other places. One good construction would be a uniform load over one-half of the span. The curve of equilibrium for such a load, on the left half of the arch of Fig. 10, is represented in that figure. The values of the two vertical components of the abutment reactions will be the sums of the components for each load, and the amount of H for the whole load will be the sum of the separate H's. Lay off, therefore, on a vertical load line, the given weights in order, and, by taking moments or otherwise, determine and lay off the two vertical reactions, so that these external forces shall come in order down and up the line, as explained in § 32.

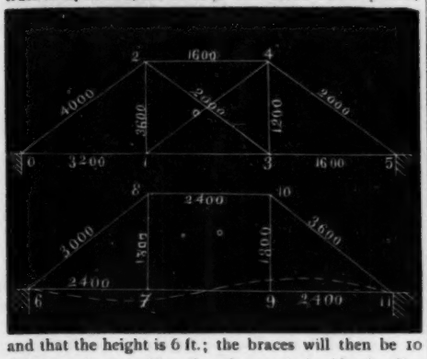
Multiply each numerical factor which belongs to H by the number of units of weight which are placed on the point to which the factor refers, add up the products and plot the resulting value of H horizontally from the point of division between the two vertical reactions. Lines connecting the points of division between the weights with the free extremity of H will be parallel to the respective sides of the curve of equilibrium. Since this curve begins at one springing, and passes round in the general direction of the arch to the other springing, we can at once see on which side of the vertical line to lay off H.

54. For example:—Let us draw the curve of equilibrium for an arch of 100 ft. span, 20 ft. rise, whose weight is at present for simplicity's sake neglected, and carrying weights of 3 tons, 2 tons, 4 tons and 2 tons, at the end of the 3d, 6th, 8th, and 9th, division from the left, of ten equal horizontal divisions, as shown in Fig. 11, where the numbers denote the weights and the points of division above mentioned. The supporting force on the left will be

(*To be continued.*)

THE TRAPEZOIDAL TRUSS WITHOUT COUNTERS.

The trusses which are here illustrated are often used for spanning moderate openings, the verticals being of iron and the remaining pieces of timber. We have thought it would not be uninteresting, to those of moderate acquaintance with the analysis of trusses, to consider what are the stresses on the several members under a given load, and more particularly to make a comparison of the two trusses under a partial load. To simplify calculations and avoid fractions let us suppose that each truss is 24 ft. in span, divided into three equal panels,



and that the height is 6 ft.; the braces will then be 10 ft. long. A supposition that the steady load is 1800 lbs. on each joint, and the travelling load 3600 lbs. per joint, will serve our purpose.

As the trapezoidal truss requires no counter-bracing under an equal load at each joint, the horizontal thrusts of the end braces balancing one another, a complete load of 5400 lbs. at each joint will cause the same stresses in either truss. The reaction at one abutment being 5400 lbs., the thrust on the brace will be $5400 \times \frac{10}{6} = 9000$ lbs., and its horizontal component, compression in the upper member, tension in the lower member, will be $5400 \times \frac{8}{6} = 7200$ lbs. The tension on either vertical rod will be 5400 lbs., and this force might as readily have been decomposed at the upper end of the vertical into the stresses on the top chord and the brace. The handiest rule, as it seems to us, when we have a force on one member, and desire to find the magnitude of its component along another member which meets the first one, is, to divide the given force by the length of the piece over which it came, and multiply by the length of the piece in which the stress is sought. The operation is equivalent to multiplying by the cosine, tangent or secant of an angle, as the case may be, and relieves one from the consideration of the particular function of the angle required.

If the counter-braced truss carries 3600 lbs. of travelling load at the left-hand joint only of the lower chord, and this lower chord is considered as possessing no stiffness at the joints, the loaded point 1 will tend to drop, carrying with it the joint 2; therefore, 4 will tend to rise, so that the diagonal 2-3 will be shortened, and we are obliged to insert the timber strut 2-3 to keep the truss in shape. Of the 3600 lbs. at 1, two-thirds will be supported at 0 and one-third at 5. The thrust on 0-2 will then be $2400 \times \frac{10}{6} = 4000$ lbs.; the tension on $0\text{-}1 = 2400 \times \frac{8}{6} = 3200$ lbs.; the thrust in 4-5, from the reaction at 5 must be 2000 lbs.; or one-half that in 0-2; the tension in 3-5 = 1600 lbs. = compression in 2-4; 2-3 carries the same one-third of the weight which goes to 5, and its compression is therefore 2000 lbs., as in 4-5, while its horizontal component along 3-0 will be 1600 lbs.; the tension in 1-2 is 3600 lbs., and in 3-4, 1200 lbs. It is manifest therefore that the horizontal component of the thrust of 0-2 is balanced by those of 2-3 and 4-5 combined, 2-3 resisting what it can, and the remainder acting through 2-4 and 3-5. Of course 1-4 is inactive until the load shifts to 3. These stresses are placed on the sketch.

If 3600 lbs. is placed at 7 on the other truss there will be a similar tendency towards deformation of the middle panel, and this tendency must be resisted by the stiffness of the beam used for the lower member. This piece must therefore be continuous from 6 to 11. When 7 is slightly depressed the tension on 7-8 carries 8 down also. Then 10 must rise, for the pieces 6-8, 8-10, and 10-11, being held at 6 and 11, make a sort of balance beam, the piece 8-10 turning about its centre. As 10 rises, it causes, by tension on 10-9, a bending upwards of the lower member at 9, so that the lower chord tends to assume the form shown by the dotted line. As the vertical force at 10 must equal that at 8, and as the bending of the beam upwards at 9 must be the same in amount as the bending downwards at 7, it is evident that one-half of W, or ½ of 3600 lbs., is carried by the beam at 7 *as a beam;* that the other ½ W is carried by the vertical rod 7-8; and that an equal upward force, required to balance it at 10, will, by tension of ½ W on 9-10, bend the lower chord upwards at 9.

The stresses on this truss will be, therefore, 1800 lbs. tension on 7-8 and 9-10, $1800 \times \frac{10}{6} = 3000$ lbs. compression on 6-8 and 10-11, and $1800 \times \frac{8}{6} = 2100$ lbs. compression on 8-10, and tension on 6-11. From the pieces 6-8 and 10-11 we get a reaction or supporting force of 1800 lbs, on each of the abutments. The member 6-11 acts as a beam under a weight of 1800 lbs, at 7 and an equal but upward force at 9. A point of contraflexure will therefore exist midway between 7 and 9, so that the beam may be treated one of twelve feet span carrying a load of 1800 lbs. at eight feet from the abutment. The necessary supporting force at 6 will then be ⅓ of 1800 lbs. or 600 lbs., which, added to 1800 lbs, the vertical component of 6-8, gives 2400 lbs., total reaction as required for a weight of 3600 lbs. at 7. Likewise at 11 we have an upward force of 600 lbs. from the pull of the rod 9-10, and the total supporting force at this abutment will be 1800 — 600 = 1200 lbs.

The bending moment will be a maximum at the point of application of the force, and its magnitude will be found by multiplying the amount of weight carried by the beam to the abutment by the distance 6-7 or 9-11; the moment therefore is $600 \times 8 = 4800$ ft. lbs., which must be resisted by the section of the lower chord at 7 and 9. As at the point of contra-flexure in mid span one part of the beam carries the other, the shear there will be 1200 lbs. The piece 6-11 must also resist at the same time the tension due to the steady load and a travelling load on one joint, or 4800 lbs.

It is apparent that, in this example, a full load causes greater direct stresses in the pieces than does a partial load, but with a light steady load and heavy travelling load such may not be the case. As 6-11 is generally made a continuous timber we may avail ourselves understandingly of its stiffness, if we please, and leave out the counterbraces.

TRANSMISSION OF POWER BY ELECTRICITY.

At the eighth annual meeting of the Iron and Steel Institute, at London, March 20 to 22, the inaugural address was delivered by Dr. Siemens. After speaking at some length upon the importance of an enlightened superintendence and direction of metallurgical works, of obtaining labor upon reasonable terms, and of cheap fuel, for success in the production of iron and steel, he throws out some suggestions as to possible utilizations of power now allowed to go to waste which we have thought it expedient to reproduce. He said "the introduction of the steam engine, towards the end of the last century, changed the industrial aspect of the world in causing manufactories to be massed together in great centres, and this tendency has been still further augmented in consequence of the construction of canals and railways, which enable us to bring together the raw material and to disperse the manufactured product at a comparatively low cost. It is not unreasonable, however, to expect that a certain reaction in this process of centralization will gradually take place, because, in consequence of ever increasing competition, the advantage of utilizing natural forces, which we could afford to neglect during a period of general prosperity, becomes again an essential element in determining the very lowest price at which our produce may be sent into the market. The advantage of utilizing water-power applies, however, chiefly to Continental countries, with large elevated plateaus, such as Sweden and the United States of North America, and it is interesting to contemplate the magnitude of power which is now for the most part lost, but which may be, sooner or later, called into requisition.

"Take the Falls of Niagara as a familiar example. The amount of water passing over this fall has been estimated at 100 millions of tons per hour, and its perpendicular descent may be taken at 150 feet, without counting the rapids, which represent a further fall of 150 feet, making a total of 300 feet between lake and lake. But the force represented by the principal fall alone amounts to 16,800,000 horse-power, an amount which, if it had to be produced by steam, would necessitate an expenditure of not less than 266,000,000 tons of coal per annum, taking the consumption of coal at 4 lbs. per horse-power per hour. In other words, all the coal raised throughout the world would barely suffice to produce the amount of power that continually runs to waste at this one great fall. It would not be difficult, indeed, to realize a large proportion of the power so wasted, by means of turbines and water-wheels erected on the shores of the deep river below the falls, supplying them from canals cut along the edges. But it would be impossible to utilize the power on the spot, the district being devoid of mineral wealth or other natural inducements for the establishment of factories. In order practically to render available the force of falling water at this, and the thousands of other places under analogous conditions, we must devise a practicable means of carrying the power to a distance. Sir William Armstrong has taught us how to carry and utilize water-power at a distance, if conveyed through high-pressure mains, and at Schaffhausen, in Switzerland, as well as some other places on the Continent, it is conveyed by means of quick-working steel ropes passing over large pullies. By these means, power may be carried to a distance of one or two miles without difficulty. Time will probably reveal to us effectual means of carrying power to great distances, but I cannot refrain from alluding to one which is, in my opinion, worthy of consideration, namely, the electrical conductor. Suppose water-power to be employed to give motion to a dynamo-electrical machine, a very powerful electrical current is the result. This may be carried to a great distance, through a large metallic conductor, and there be made to impart motion to electro-magnetic engines, to ignite the carbon points of electric lamps, or to effect the separation of metals from their combinations. A copper rod of 3 in. in diameter would be capable of transmitting 1,000 horse-power a distance of say 30 miles, an amount sufficient to supply 250,000 candle power, which would suffice to illuminate a moderately sized town. The use of electrical power has sometimes been suggested as a substitute for steam power, but it should be borne in mind that so long as the electric power depends upon a galvanic battery, it must be much more costly than steam power, inasmuch as the combustible consumed in the battery is zinc, a substance necessarily much more expensive than coal; but this question assumes a totally different aspect if in the production of the electric current a natural force is used which could not otherwise be rendered available."

There does not seem to be anything impracticable in Dr. Siemen's suggestion that the work of a water power may be converted into electricity, conveyed to a distance by a suitable conductor, and then reconverted to give motion to machinery. Whether the time will soon come when it will be thought expedient to inaugurate such an enterprise is another question. It is but a short time since dynamo-electrical machines have been so developed as to render such a step possible, but they can now be constructed of any desired power. The Gramme Machine may be built for about one hundred dollars per horse power, a not unfavorable comparison with a steam engine, and it is a good example of a reversible engine, that is one which may be worked either way. If mechanical power is applied to the machine it is converted into electricity, while when a current is passed through the coil, it is converted into motion.

The change of energy from one form to another in this way is, however, practically attended with considerable loss of work, and such a series of steps, from the original source of power to the distant place where local circumstances make it desirable to establish the factory, would only be profitable, if at all, where the power was cheap and could not be utilized otherwise. In the case of a water power, the force of the water must first be brought upon a wheel, which may be made to develop from 75 per cent. to 80 per cent. of the energy of the water which passes through it. The Gramme machine will convert some 90 per cent. of the power applied to it into electricity. Two of these machines have been con-

nected by a short circuit, and it has been found that the second machine will give out 50 per cent. of the mechanical work applied to the first.

Then we have the additional loss from the resistance of the long conductor, which resistance enters into a formula as a divisor; that is, if C represents the current, E the electro-motive force and R the resistance, $C = E \div R$. The resistance varies as the length of the conductor and inversely as the cross-section. It will be seen to affect the available power much as friction in a water-pipe lowers the dynamic head, or wire drawing diminishes the effective pressure of steam. If the product of these various ratios seems to give a very small percentage of the original power finally obtained, we have only to consider how little of the calorific power in coal we succeed in converting into work in our best steam engines, to make it appear not so bad a result after all.

This idea of the conveyance of power to a distance by means of electricity has been broached before, and some have thought that by a ramification of wires through a city, they might deliver power at small manufactories wherever desired. The difficulty in such an application of the idea to practice is, that the electric current will take the path of least resistance; that machine most favorably situated would feel the larger part of the force, would be driven at too great a speed, and then the connections would be melted and burned off by the intensity of the stream. Electricity cannot be distributed like water and gas.

ANOTHER PLAN FOR IMPROVING NIAGARA.

By a somewhat curious coincidence another gentleman has turned his thoughts towards making the mighty cataract of Niagara useful to man. The *Ottawa Free Press* contains the following:—

"A letter has recently been addressed to his Excellency the Governor General, by Mr. Horace H. Day, a gentleman who owns the American side of Niagara Falls, on which side the water-power much exceeds that of the Canadian fall. Mr. Day recommends the utilization of the vast water-power by the establishment there of manufactories for spinning and weaving cotton cloth. When our ship canals, and eventually the Pacific Railway, are completed, the subject of cheap production may have a measure of interest to our manufacturers not now even thought of. The chief points of Mr. Day's scheme are the following; and should his ideas as yet fail to be appreciated, we may call to mind Geo. Stephenson, fighting his railway enterprise through amid the ridicule of parliament and people, and Mr. Muntz going humbly from one ship owner of London to another, vainly asking permission to apply, at his own expense, a coat of his metal to the bottoms of their ships:

1. The formation of compressed air, by means of the water-power, and its appliance to drive the machinery of cotton factories, placed where convenient, the air being conveyed in pipes and applied to the common steam-engine.

2. The manufacture, by this means, of cotton cloth, so near to the producing points of the raw cotton and of the food staples as materially to lessen the cost of production.

3. The loading and unloading of vessels by means of the same cheap hydraulic power, the only expense of which is, of course, the erection of the apparatus.

4. The gray cotton cloth being so manufactured, its transportation (when the canals are enlarged) in seagoing vessels, direct from the point of production to England, there to undergo the finishing process of bleaching and printing, and to be thence distributed to the markets of the world.

We understand that his Excellency has promised Mr. Day to lay his communication before the Dominion government, and to forward a copy of it to the Secretary of State for the colonies, for the consideration of her Majesty's government."

If we mistake not, this gentleman has for a number of years been interested in the projects for the transmission of power by means of compressed air. Apparatus for this purpose was on exhibition several years ago at Portland, Maine, and the experiment was successfully tried on a small scale in the neighboring town of Brunswick. At that place an air compressor was driven by a turbine, and the compressed air, after being cooled by water, was distributed through the streets by pipes laid in the ground. A few small engines were run by this means, but there was not enough business done to make the venture profitable. The loss of pressure was said to be very slight in going a mile, and we could see no reason why small powers might not in this way be distributed to users and the project be remunerative, where water power was accessible and cheap.

THE citizens of Detroit, Michigan, are discussing with renewed interest the proposition to aid in the construction of a tunnel under the river at that point. They begin to feel that, unless definite steps are taken by them soon to encourage its location there, a crossing will be made elsewhere and the prosperity of the city will receive a serious shock. The proposition which is now strongly urged contemplates giving $500,000 outright, as a *bonus*, to parties who will construct a tunnel for the use of the railroads; the estimated cost is between $2,500,000 and $3,000,000.

THE notification of the Philadelphia & Reading Railroad Company to their locomotive engineers that they must choose between working for that company and continuing members of the Brotherhood was followed by the withdrawal of some two hundred and fifty engineers from the company's service. Their places have been supplied and business has been but little hindered. This action of the Philadelphia & Reading Company, rendered necessary, as it was thought, by the recent strike on other roads, must have dealt a severe blow to the engineer's organization.

DR. SIEMENS in his recent address does not advocate any attempt at comprising in the curriculum of technical schools a practical working of the processes which the student would have to conduct in after-life. He says that "the practice taught in such establishments is devoid of the commercial element, and must of necessity be an objectionable practice, engendering conceit in the mind of the student, which will stand in the way of the unbiassed application of his mind to real work. Let technical schools confine themselves to the teaching of those natural sciences which bear upon practice, but let practice itself be taught in the workshop and in the metallurgical works."

The Cleveland *Trade Review* says: "The Globe Iron Works was lately awarded a contract for a copper boiler, eighty feet long and six feet in diameter, with a spherical head, the material used to be pure copper, five-eighths of an inch in thickness, and costing about $17,000. The boiler will be used in impregnating timbers for shipbuilding, docking and piling by the Thilmany process, which has been adopted by the general government."

This process as described in a pamphlet issued by the proprietors of the patent, consists of the introduction of Sulphate of Copper under pressure, followed or preceded by Chloride of Barytes, when there takes place in the wood a chemical reaction, an insoluble Sulphate of Barytes and a Chloride of Copper being formed.

THE PUBLIC WORKS OF INDIA.*

Before the Roman invaders had commenced the lines of communication and of defense that gave form to the subsequent local divisions of England, the Indian Rajahs were at work in storing the copious rainfall that descended on the mountain ranges of their country, and in providing the means of irrigation that should turn desert into garden. In various parts of India exist numerous old native works, many of which bear witness to great engineering skill, exercised at a remote antiquity. The most important of these are in the southern part of the peninsula, where innumerable tanks, containing from a hundred million of cubic yards of water downwards, store supplies for the summer maintenance of the flow of the great river channels. Many of these noble works have stood for centuries. Many of the weirs that bridle the discharge of rivers are built on sandy foundations, without any rock or sound stratum on which to base them, and yet have been constructed with such art as to modify the practice of our own engineers. Our latest modes of sinking the foundations of river bridges by means of iron cylinders, has been anticipated at a date of unknown antiquity, by the simple contrivance of wells or shafts lined with bricks, built on the surface, and sunk to the required depth by workmen who undercut the sides of the shaft, and thus facilitated the gradual descent of the brick tube. Till within the last thirty years very little has been done by the Indian government even for keeping these important works in repair. When Sir Arthur Cotton was ordered to report on irrigation works in 1836, he found many thousand tanks in every state of disrepair or ruin, scarcely any in good repair, and not one of British construction. Over the greater part of India are found patches of land irrigated by hand, or by the aid of bullocks, raising water from wells, rivers, or lagoons. The *ne plus ultra* of simplicity, and, indeed, the most effective application of human labor was attained by the contrivance called a *picottah*, which is as old as anything with which we are acquainted in India. The cost of raising water by this contrivance, which is about the same as the cost by the use of bullocks, to a height of from twelve to fifteen feet, is calculated at about 3,000 cubic yards to the pound sterling.

The Nizam's territory, Mysore, and the Carnatic, are covered with thousands of tanks. In the fourteen districts of Madras, according to Mr. Markham's statement, there are said to be 43,000, all of native origin, with probably 30,000 miles of embankments, and 300,000 separate masonry works. The revenue dependent on tanks was £1,500,000 per annum; yet in 1853 not one new tank had been made in Madras by the English, although many had been allowed to fall into disrepair. The area of the province of Madras is 139,698 square miles. The population in 1871 was 31,597,872 souls. In Mysore, until quite recently, the maintenance of the ancient tanks was far from satisfactory. The mode of formation of these reservoirs differs according to the features of the country, and the most remarkable tanks may be described as cases in which man has so far availed himself of the provisions of nature, as to form large artificial lakes by barring the exit of a stream from a mountain valley. In some cases descending terraces of land are occupied by a succession of reservoirs; the upper filling first from the rains, and the surplus water gradually filling the series as they descend the slope. In other instances long slopes are embanked on three sides, the included space forming a storage area for a supply of water adequate to the local demand. Some tanks of this description are of great antiquity. The Veranum tank in South Arcot is still in full operation after an existence of fabulous duration. It is named after a famous rajah, its constructor. It has an area of thirty-five square miles, and is confined in the lower part by a *bund*, or embankment, twelve miles long, and about twenty feet high. It will contain one hundred million cubic yards of water, and it secures an annual revenue of £11,450. In 1827, when Sir Arthur Cotton was ordered to inspect it, he found it in utter disrepair, and the people dependent on its supply, were nearly in a state of rebellion from its neglect. The canal from the Coleroon, twelve miles long, by which the tank is fed for six months out of the year, had been allowed to fill up to the depth of six feet, so that it had only two feet of water flowing through it, instead of eight. The estimate of £3,500 for immediate repairs for a work of this extreme importance was rejected by the government of Madras; and it was not until 1833, when the discontent of the people had reached such a pitch that it was feared it would be necessary to send troops into the district, that substantial repairs were effected.

The Chembumbankum tank, in Chengalpat, looks like a picturesque natural lake. The embankment is more than three miles long, and the tank supplies water for the irrigation of nearly 10,000 acres of rice cultivation. Its safety during floods, is secured by six waste weirs (called *calingulas*), which give a total width of 676 feet of esape channel; a width which is within twenty feet of that of the open water-way of the Thames under London bridge. The supply is merely from rainfall and local drainage. An enlargement of this fine tank, at a cost of £11,000, was sanctioned in 1867, and the excavation and earthwork were completed in 1873. The Kaveripank tank, in North Arcot (we may mention that almost every writer uses a different spelling of his own) is also of great antiquity. It is fed from the Pallair river, and has an embankment nearly four miles long, revetted along its entire length with stone. It irrigates nearly 7,700 acres. In 1872 the water rose higher within it than had been the case for many years, and several serious slips in the ground occurred in consequence.

In Mysore there are few very large tanks, owing to the undulating nature of the country, and the irrigation of the district depends either on the Cauveri and its tributaries, or on numerous chains of small tanks. In

* From the British Quarterly for April.

these the process of silting up is continually going on, and constant inspection and repairs is requisite. During 1872–73 as many as 249 tanks were breached in this province. By the tank restoration scheme now in force the irrigation department annually selects a certain number of tanks for immediate repair, brings them up to a certain standard, and then leaves them to be kept in repair by the ryots, under the directions of the revenue officers. In this way all the tanks of the province are being gradually dealt with.

In the Bombay Presidency the Ekruk tank is situated on the Adela, a tributary of the Blaina, four miles north of the town of Sholapur. A dam of earthwork, with masonry flanking is thrown across the valley drained by the stream. This embankment is 7,200 feet long, and attains in the deepest part the formidable height of 72 feet. A lake has thus been formed with an area of six and a half square miles, the filling of which submerged five villages, two of which were in the territory of the Nizam. The area watered by three channels leading from this tank amounts to 35,840 acres. The water was supplied free of charge in the year 18,2–73, being the first year after the partial completion of the works.

In Rajputana exist the noble tanks known as Lake Rajsumund and Lake Jeysumund. The former is twenty-five miles north of the capital, Oodipur, and is situated on the declivity of the plain, about two miles from the base of the Araoulli range. The *bund* or dam forms an irregular segment of a circle, nearly three miles in length, encircling the water except on the north-east and north-west edges of the lake. It is entirely faced with white marble, sustained by an enormous embankment, which it was the design of Raja Raj Sing, who constructed the work, towards the end of the seventeenth century, to plant with trees. A flight of marble steps leads down from the *bund*, which supports a temple built in honor of Kankeraoli, one of the seven forms of Krishna. The temple is ornamented with sculpture, and contains the pedigree of the founders family, inscribed in conspicuous characters. The work was named after its designer, Raj Sumund, or royal sea, and cost £1,150,000. Lake Jey Sumund, the Sea of Victory, was constructed by Jey Sing, the successor of Raj Sing, and is said by Mr. Tod to be the largest lake in India. Its circumference is stated to be not less than thirty miles. A perennial stream, flowing from the mountains, had formed a lake called the Dheybur Pool. Jey Sing threw a dam across a break in the mountains, between two natural buttresses of rock, and then created this little inland sea. On the *bund* was erected a palace for his favorite queen, who bore the name of Comala-devir. This lake supplies water for the irrigation of a large area of rice-growing land.

The irrigation works of India comprise three different classes of works, the applicability of either of which to the wants of a district depends on the physical conformation of the country and on the rainfall. In the mountainous districts, where the rainfall is often enormous, are constructed those great works for the storage and gradual distribution of the supply, of some of which we have given particulars. At the heads of the great river deltas, on the other hand, are constructed weirs, or *annicuts*, by means of which the volume of the river is headed back, in the dry season, to a height sufficient to allow of the distribution of its waters by canals over the area of the delta. Intermediate between these most land-ward and most sea-ward works directly constructed for the facilitation of irrigation, are to be found various kinds of canals, those of derivation, of diversion, and of distribution; many if not most of which are also adapted for purposes of navigation, and may thus most properly be regarded as a portion of the communications of the country, and referred to when we have spoken of the more important question of the facilities afforded to our military and civil administration, as well as to the commercial intercourse between various cities and districts, afforded by the railways.

The annual rainfall of India has been made a subject of systematic study. In Southern India Major-General Richard Strachy and Dr. Brandis, and in the northern districts Mr. Blanford, have laid down lines of equal average annual rainfalls, which map out the peninsula in parallel zones. In the northwest exists an arid region, including Sind and half the Punjab, where the nominal annual rainfall is less than fifteen inches. Here irrigation is essential to the existence of the population. Around this arid region exists a belt of country varying from 100 to 200 miles in width, which includes Delhi and Agra, and has been named by Dr. Brandis the Northern Dry Zone. The annual rainfall in this district is from fifteen to thirty inches. A similar district, called the Southern Dry Zone, covers the centre of the southern part of the peninsula, extending from Nasik to Cape Comorin, with an extreme breadth of about 190 miles. Irrigation is an absolute necessity in these dry zones. A fourth region, with a rainfall of between thirty and sixty inches, includes the upper part of the valley of the Ganges, Central India, and the eastern coast of the Madras Presidency. This also much depends on irrigation. The fifth region, comprising the deltas of the Mahanadi and of the Ganges, and the lower part of the Ganges valley, has a rainfall of between sixty and seventy-five inches. In this favored zone of country irrigation is no longer absolutely necessary for the cultivator, except in years of unusual drought; but the power of regulating the supply of water, by irrigation and by drainage, is an element of agricultural wealth in every district. In some it is absolutely indispensable; in all it is of inappreciable value. The two remaining regions are the zones of excessive rainfall; one extending from the mouth of the Irawadi, along the east coast of the Bay of Bengal, up the valley of the Bramahputra, and along the skirts of the Himalayas; the other along the west coast of the Peninsula, from the sea shore to the summits of the Ghauts. These zones are divided on the rainfall maps of India into two sub-zones, in the drier of which the annual rainfall is from seventy to one hundred inches, while in the wetter it exceeds one hundred inches. The care of the engineer in these districts is required to insure the safe and gradual discharge of the abundant supply of water, rather than for any other hydraulic purpose.

The magnitude of the natural features which map out the physical geography of India, and prescribe the natural limits for the work of the engineer, is so vast as to be oppressive to the imagination. The united areas of the basin of the Ganges and Bramahputra, which rivers, draining the southern and northern slopes of the Himalayas, unite in the enormous delta formed by their confluent streams, amount to a total of 762,000 English square miles. The length of the main stream of the Ganges is 1,514 miles, that of the Bramahputra 1,800 miles. The basin of the Indus, the course of which is also 1,800 miles long, covering 372,000 square miles, was the abode of the first civilized race in India, and is the region where irrigation was first practized in that country. The Godaveri has a course of 898 miles, and drains about one-tenth of the area of India, its basin being computed to cover 112,000 square English miles. Rising in the fourth of the rainfall zones, in the high country of Central India, it is fed by an average rainfall, according to Sir Arthur Cotton, of forty inches, and pours two hundred milliards of cubic yards of water annually into the bay of Bengal. At the end of the dry season its hourly discharge is about 300,000 cubic yards of water. But in extreme floods it rises thirty-one feet in vertical height at the apex of its delta, and then carries down 180 millions of cubic yards in an hour, a discharge which, if kept up for a month, would be equal to six times the October flow of the Nile, at the season when that river is at its height. The length of the course and area of the basin of the Irawadi are intermediate between those of the Indus and of the Godaveri, being respectively 1,060 statute miles, and 150,800 square miles. The Krishna, the geological delta of which joins that of the Godaveri, has a course of 800 miles, and drains a watershed basin of 95,500 square miles. The length of the Mahanadi, the delta of which river forms a sensible protuberance on the long line of coast reaching from the mouths of the Godaveri to those of the Ganges, is 520 miles, and the basin covers an area of 43,800 square miles. Taken altogether, the basins of the rivers that discharge their waters into the Bay of Bengal form an aggregate of 1,441,900 square miles; while those of the rivers that enter the Arabian Sea amount to 629,900 square miles. The difference between the data of physical and political geography is illustrated by the comparison of the hydrographic area of 2,071,500 miles thus composed, with the 943,406 square miles which form the total area of the twelve provinces which constitute British India. The aggregate length of the twenty-four principal rivers of British India, according to the map contained in the Report of the Moral and Material Progress and Condition of India during the years 1872–73, is 14,238 miles. The importance of the responsibility that weighs on the government engineers may be illustrated by the remark that a careful watch over this main channel system of 14,000 miles forms but a small part of the duty of those who are looked to, not only to maintain, but to improve the drainage, the irrigation, and the internal water communication of this vast empire.

To be continued.

CO-ORDINATE SURVEYING.*

BY HENRY F. WALLING, C. E.

Continued from page 102.

Outside of cities and larger towns, the instruments usually employed in surveying are the chain and compass. The method is to perambulate the boundary line of the tract to be surveyed, taking the magnetic bearings with the compass, and measuring with the chain the lengths of each side of the polygon forming the boundary.

IMPERFECTION OF THE COMPASS.

Now, provided the bearings thus taken were precisely measured angles from fixed parallel meridians, whose directions could always be easily ascertained, when a re-survey should be needed, no better method of noting directions could be desired. But this is far from being true. The magnetic force to which the direction assumed by the needle is due, is quite irregular in its action, changing its direction continually, backwards and forwards, even during the different hours of the day, while larger oscillations extending sometimes to many degrees of arc take place in irregular cycles, perhaps one or two centuries in duration. And this is not all. In regions containing metallic deposits, especially magnetic iron ore, very irregular and powerful local disturbances of the magnetic force arise, causing the needle to take widely different directions, even at points in close proximity to each other, thus destroying parallelism of action, and rendering the compass quite useless for ascertaining true directions.

Beside the uncertainty of the magnetic meridian, there is an incapacity of precision in the use of the compass for measuring angles. The needle must swing clear of the graduated limb, and cannot be suspended for field use, with very great delicacy. In practice it is usually imposible to read a magnetic bearing with greater precision than to the nearest 10 minutes of arc.

THEODOLITE AND SURVEYOR'S TRANSIT.

The theodolite and the surveyor's transit are instruments of far greater precision and are generally used in cities, and for more valuable farm lands, also for engineering works, roads, railroads, etc. Those in ordinary use, measure angles to single minutes.

In land surveying, the common method of using these instruments is to measure the angles formed by the sides of the bounding polygon with each other, and sometimes, for verification, with one or more diagonals. The compass needle, usually attached, affords an approximate means of ascertaining azimuths, but with no more precision than with the ordinary compass. It is accordingly, quite as difficult to retrace obliterated boundaries with these instruments as with the compass, unless one or more well-defined lines remain for reference.

SOLAR COMPASS.

The solar compass now used in the surveys of the public lands at the West, for running out the parallel and range lines is a great improvement upon the magnetic compass in the accuracy of its azimuths if not in the precision of reading minute angles. The direction of the sun, with proper adjustment of the instrument for the latitude of the place and declination of the sun and hour of the day, affords of course, a reliable means of obtaining the true azimuth of an observed line with as much precision as the mechanical construction of the instrument permits. The use of the solar compass, however, is limited to sunshining or slightly cloudy days, the middle portions of which, moreover, are unfavorable to accurate observations, and at best, the precision of

* From the Transactions of the American Society of Civil Engineers.

its angular measurements is much inferior to that attainable with the transit. Nevertheless, with the preliminary surveys of wild lands, where no trigonometrical survey has been made, and where rapidity and economy are required, as in the government surveys of western lands, it is a very convenient and useful instrument.

MEASUREMENT OF DISTANCES.

The direct measurement of distances is attended with even more difficulty than that of the determination of directions. It is accomplished by the repeated application of the chain, tape or measuring rod, as nearly as possible, upon the line to be measured. Passing over inaccuracies in the length of the measuring standard arising from imperfections of construction, inequalities or temperature, changes of length by stretching, kinking, etc., the difficulties of making the direct applications are frequently quite serious. It often happens that access to all parts of the line to be measured is difficult, if not impossible. In fact, the boundaries of improved properties are generally indicated by walls, fences, hedges, ditches, etc., which occupy a considerable width upon the ground, being partly upon either side of the dividing line, upon which it therefore becomes impossible to apply the measuring standard. In such cases, it is usual to measure the opposite sides of an imaginary parallelogram, equal offsets being made at the ends of the line, and the measurements effected between the offset points. The offset angles are quite frequently estimated by the eye, and brought as nearly as possible to right angles. Even if these angles are instrumentally measured, the operation becomes complicated, thus increasing the liability to error. Impassable obstacles along boundary lines are of frequent occurence, and various expedients, more or less complicated, are resorted to for ascertrining the distances through them. The difficulties of measuring accurately over uneven ground, requiring a careful and laborious use of the plumb line, the avoidance of sagging or unequal stretching when the chain is used, the exact marking on the ground of the end of the measuring standard, etc., are familiar to all land surveyors.

MEASUREMENTS OF ANGLES.

It is easy to see that measurements of angles with good instruments can be performed with far greater ease and precision than the measurements of distances by the ordinary methods. Either mode of measurement is merely a determination of *ratios*. Thus, when we measure the length of a line by direct application of a standard length upon the ground, we simply ascertain the ratio between the length of the measured line and that of the chain. So, if we measure the three angles of a triangle, we know by a simple computation, the ratio of its three sides to each other. The percentage of error in the ratios, as found by either method, is much less in the measurement of angles with good instruments; for although the distances which are compared together in this measurement, namely those marked in degrees along the limb of the instrument used, are many times smaller than those compared together in the measurement of distances upon the ground, the nicety of the mechanism and the ease of the verification by repetition admit a precision quite unattainable in actual ground measurements, except by slow and laborious processes.

TRIGONOMETRICAL SURVEY.

In the trigonometrical survey, this superiority of angle measurement is practically recognized. Convenient points are selected, at suitable distances from each other, where the angles between imaginary lines, joining adjacent points can be measured. The whole area to be surveyed is cut up by these lines into a network of triangles, and the ratios of the sides of these triangles to each other are determined by measuring the angles between them. Then, when we ascertain the length of any one side of any one triangle, we can compute all the sides of every triangle, or the distances from point to point throughout the whole survey.

DEGREE OF ACCURACY ATTAINED.

The accuracy of the result, accordingly, depends upon the precision with which this one side or base line is measured, as well as upon the accuracy of the angle measurements. It is usual to verify the whole of the work by measuring another base line in a distant part of the network of triangles. For example, in the Coast Survey work, a base line was measured at Fire Island, on the south side of Long Island, in 1834; another in Attleborough and Sharon, Massachusetts, in 1844; and another near the village of Epping, in Columbia, Washington county, Maine, in 1857. The distance between the Fire Island and Massachusetts bases, along the axis of triangulation, was 230 miles, and between the Massachusetts and Epping bases 295 miles. The length of the Fire Island base, 8715.942 metres, or 5.415 miles, as actually measured, varies from the length, as computed from either of the other two bases, by less than 0.07 metres, or 2.75 inches; and the probable error of any computed line between these two bases is shown by careful analysis not to exceed 1-288,000 of its entire length. This proportion of error to distance amounts to 0.22 inches in a mile, or a little less than 2 feet in 100 miles.

This degree of accuracy indicates the wonderful skill which has been attained in the construction and use of instruments both for the measurement of base lines and of angles. Thus, if we compare the actual distance upon the limb of a theodolite, 30 inches in diameter, which corresponds to an error of 1-288,000, which we will suppose to be all thrown into one of the three angles of a single well conditioned or nearly equilateral triangle, we shall find it equivalent to about 1-20,000 of an inch,* being about 0.71 seconds of arc.

The percentage of error here developed is so small that it would not practically vitiate the measurement of lands even in the most valuable localities of great cities.

SUPERIORITY OF THE TRIGONOMETRICAL METHOD.

The degree of precision commonly attained in direct measurements of distances by ordinary methods falls very far short of this, and even of that attainable in angle measurements with the ordinary surveyor's theodolite or transit.

It follows that accuracy, even in common surveying, would be promoted by using the method of triangulation for ascertaining ratios, whenever practicable or convenient, in preference to the common methods of traverse surveying. In the survey of a field, or tract of land, for example, triangulation from one or two judiciously selected and carefully measured bases would give the positions of the corners and other objects with greater accuracy and far less labor than the usual routine of perambulating the outside boundaries, which is now taught in treatises on surveying and generally practiced by surveyors.

ADVANTAGES OF COMBINING SURVEYING WITH GEODESY.

With the facilities afforded by the Coast Survey triangulations, when carried to the tertiary stage, it is not difficult to perceive that a general method of determining the positions of points by co-ordinates might be established, and that while determinations thus made would be far more satisfactory and definite than those obtained by the ordinary methods of surveying, they would involve no more labor. Under such a system, the field work might consist of such a combination of triangulation and traverse surveying as would be found most convenient under the special circumstances.

To carry out such a system, the trigonometrical stations should be located so near together that two or more of them would be available for any subsequent local survey. If not otherwise visible, there should be convenient arrangements for the temporary erection of signals upon stations to indicate their positions, making them visible from adjacent stations.

TRANSFORMATION OF CO-ORDINATES.

While for geographical purposes, the great co-ordinate planes already described are the most suitable for reference, simplicity and convenience would be promoted by transforming this general co-ordinate system into numerous plane rectangular systems of a point by giving its terrestrial latitude and longitude, we would give its "latitude and departure." or its co-ordinates, from the zero point or origin of co-ordinates for the containing area.

For this purpose the local areas, into which the earth's surface is subdivided, should be made sufficiently small to reduce the error which would arise from considering each separate area, or plane surface, to an inconsiderable amount. Six miles square is not far from the average area of townships in the northern, middle, western and most of the southern States. The bulge of curvature, or the versed sine of half the arc of 6 miles, would be about 6 feet. This would make the proportional difference between the straight and the curved distance, or between the length of the chord and of the arc, much less than the percentage of probable error inseparable from measurements of the utmost attainable precision in actual practice. Township boundaries, therefore, would seem to afford the most convenient divisions between separate co-ordinate systems. If, however, as is the case in a few of the southern States, no smaller civil subdivisions than counties exist, these are not usually so large that the use of a single co-ordinate system over its area would involve any important error.

DIRECTION OF AXES.

The most appropriate and convenient directions for the axes would doubtless be found in meridians and perpendiculars to them, since azimuths reckoned from the meridional axis would then conform very nearly to the true astronomical azimuth. Owing to the convergence of meridians, there would be a small variation from the true azimuth increasing with the distance from the axis, but no practical error need arise from this cause. The true azimuth, if needed, is easily computed by the formula,

$$\tan. \tfrac{1}{2} C = \sin. L \tan. \tfrac{1}{2} P,$$

in which L is the middle latitude between the origin and the point where the convergence is to be computed, P the difference of longitude between the same points, and C the convergence sought. In passing from one district to another, however, a certain degree of complication arises and it becomes necessary to take the convergence into account. We may, without practical error, consider any two adjacent districts as lying in a plane produced by developing a conical surface tangent to the earth on the middle parallel of latitude between the origin of the two districts. On this plane, the convergence of the meridional axes of small districts will conform to the above formula, and the small angle of convergence measures the change of direction between the co-ordinate systems of the two districts.

PASSING FROM ONE DISTRICT TO ANOTHER.

In the passage from one district to another, four different cases of transformation of co-ordinates arise, namely:

1st, When the origin of the new system is east and north of the origin of the old system.

It will of course, be necessary while assigning positive values to latitudes and departure in one direction to give negative values in the opposite direction; thus if north and east are to be reckoned as positive, south and west must be reckoned as negative.

(*To be continued.*)

* More exactly 0.000052 inches, for we have radius = 57.3°, nearly, in terms of arc; or, making radius = unity, 1° = 1-5738′ 1″ = 1-206,280 and 1-288,000 = 0.71″ nearly. Conversely, in terms of distance, if radius = 15 inches, 151-288,000 = 0.000052 inches.

PREVENTION OF IRON RUST.

A very important paper has lately been read before the Society of Arts by Mr. Barff, Professor of Chemistry to the Royal Academy, upon a method of preserving iron from rust by coating it with its own magnetic oxide. The facts which Prof. Barff has brought forward, and the specimens which he has exhibited, are such as to justify the belief that his discovery will prove to be one of enormous value, and that it will, indeed, render all kinds of iron-work, however much exposed to weather, or to corrosive vapors or liquids, practically indestructible and everlasting.

When an iron surface is exposed to the action of water, or of moist air, it speedily becomes covered by a film of protoxide or ferrous oxide, which consists of 56 parts by weight of the metal to 16 parts of oxygen. The ferrous oxide continues to attract oxygen from the atmosphere, and is gradually converted into another compound, the sesquioxide, or ferric oxide, which is composed of twice 56 parts by weight of iron, and three times 16 parts by weight of oxygen. The ferric oxide, in its turn, gives up some of its oxygen to the as yet unoxidized iron beneath it, and the ferrous oxide thus formed is gradually converted into ferric oxide by the access of air through the spongy layer of superficial rust which covers it. In this way the first formed film of rust exposes to the atmosphere the surface which lies below it; and hence the rust becomes a carrier of oxygen to the deeper parts of the iron, until the latter is completely corroded and worn through. Many attempts

have been made to protect iron surfaces by the application of some kind of paint or varnish; and these attempts have, of course, been to some partial extent successful. Such coatings, however, have no real adhesion to the metal on which they are placed, and are liable to scale off or to perish in a variety of ways, Even when the coating is generally sound, the smallest flaw in its continuity will give entrance to the enemy; for the rust from the exposed spot will spread laterally under the coating, and may be all the more dangerous and destructive from being partially concealed from view.

It is manifest that the evils incidental to rusting are entirely due to the unstable character of the two oxides already mentioned, which are formed spontaneously under ordinary climatic conditions. There is, however, a third oxide which possesses characteristics of a totally different kind, and which is uninfluenced, not only by moist air, but even by acids and other corrosive substances. This is the magnetic or black oxide, which consists of three times 56 parts by weight of iron, and four times 16 parts by weight of oxygen. Prof. Barff has discovered that if any iron article is exposed, at a high temperature, to the action of superheated steam, it will become covered by a film of this black oxide, of a thickness which is determined by the degree of temperature and by the length of exposure. The oxide is harder than the original iron, and adheres to it even more firmly than the particles of iron adhere to each other, so that there is a gain not only in chymical, but also in mechanical resistance. If the operating chamber is heated only to 500 degrees Fahrenheit, and the exposure is continued for only five hours, a surface is obtained which will resist emery-paper for a considerable time, and which will not rust within doors, or after any moderate degree of exposure to moisture. If the oxidizing process is conducted at 1,200 degrees Fahrenheit, and continued for six or seven hours, the surface will resist a rasp, and will bear any amount of exposure to weather. The oxidation does not affect the appearance of the surface in any other way than by turning it black. A rough forging retains its roughness, and a turned or polished surface retains its smoothness. If there should be any flaw in the coating, or if the black oxide is designedly removed from part of the surface, the common oxidation will occur where the iron is thus left unprotected. But such oxidation is strictly limited to the unprotected portion, and has not the smallest tendency either to spread laterally under the black oxide or to detach this from the subjacent parts.

Prof. Barff has as yet been limited in his operations by the want of a heating chamber large enough to treat iron articles of considerable size, but he has prepared a great number of specimens of small articles, and these have been subjected to tests of every kind. Such things as bolts, rivets, screws, door-handles, gun-barrels, water-pipes, railing-heads, cast-iron saucepans, and other articles too numerous to mention, have been left for six weeks of the recent wet weather upon a lawn at Bayswater, and at the expiration of that time were taken up absolutely unchanged, and without a speck of rust except upon parts which had been left, either by design or accident, without protection. One of the specimens shown by the Society of Arts was a long bolt, from half the length of which Prof. Barff had cut away the coating of black oxide before leaving the bolt upon the lawn. The scraped portion was covered with a considerable thickness of sesquioxide, but the coated part had remained unchanged, and it was impossible to raise the film of black oxide at the line of demarcation. The film was an integral part of the iron itself, and the one could not be detached from the other. Another specimen was the head of a pipe for collecting roof-water, which had been broken by a sledge-hammer after it was coated, and then thrown into a sink in Prof. Barff's laboratory, where not only water, but many corrosive liquids, were constantly passing over it. Rust had formed at the fractured edges, but the protected surfaces were wholly untouched.

Among the most valuable and important of the probable applications of the invention will be the protection of steam boilers and of the plates of iron ships; and Prof. Barff hopes that by certain arrangements it will be possible to operate upon very large manufactured articles without its being necessary to provide a heating chamber large enough to contain them. The applications seem almost without number. The process will be conducted at very small cost, and it will probably be employed, at no distant time, for iron goods of every description. Not only so, but it will extend the applications of iron itself to several purposes for which its liability to rust has hitherto rendered it unsuitable. Copper vessels will no longer possess any advantages for cooking, and iron saucepans will no longer need to be tinned. Leaden pipes for the conveyance of water will in all probability be entirely superseded; and there can be no doubt that new uses for incorrodible iron will every day suggest themselves. Messrs. Penn, of Greenwich, are about to undertake a series of trials for the purpose of testing the strength of the prepared articles, so that they may become able to speak with authority upon the fitness of the oxidized iron for bridge girders and architectural purposes; and Prof. Barff is himself fitting up a heating chamber of a larger size than that in which his early experiments were conducted, and will before long be in a position to furnish evidence of the commercial practicability of his process.—*London Times.*

HEALTH BOARD OF NEW YORK.

In a recent statement made by the officials of the Health Department an attempt was made to prove that in New York the death rate was much lower than in nearly all the large cities either in this country or in Europe. In order to prove this much to be desired sanitary result the mortality for the past quarter was taken as a basis for calculating the present yearly death rate. There having been 6,002 deaths within this period, and the population being estimated at 1,077,228, a rate of mortality of 22.28 per 1,000 was obtained for the entire year. No one is better aware than the gentleman who prepared this statement for the Health Board that it is incorrect and not a true exhibit of the present rate of mortality for this city for the following reasons:—In the first place, the three months just passed have proved to be unusually healthy, thanks to the extremely fine weather, consequently the past quarter is not a correct or just basis to make such a calculation; secondly, it is a well known fact that can be easily proved from the reports of the Board of Health that the excessive death rate from zymotic diseases is always from about July to October. This is in keeping with the experience of every physician in the city. The Eleventh ward has a death rate of 35 to 40 per 1,000 (yearly rate) during the heated term. While in the winter months the rate is seldom or never below 26 or 28 per 1,000. At page 236 of the last Health Report the following statement is made:—

"More than half the inhabitants are living at such a disadvantage as respects their domicile and their social state that they are comparatively incapable of resistance to the local causes of disease, and during the hottest and coldest periods of the year the more unhealthful quarters become excessively perilous to great numbers of their residents. The special insalubrity of these limited districts of uncleanliness and overcrowding is shown by the fact that children under five years of age perish at the rate of 250 to 300 per 1,000 (yearly rate) during the ten or twelve hot weeks."

From the foregoing extract from the official reports it will be at once seen how absurd it is to draw any estimate as to the actual death rate from the returns of three months, particularly when the period selected gives a much smaller rate of mortality than either the third or fourth quarters of the year.

It can hardly be disguised that this last statement of the Board of Health has been made in order to induce the public to believe that the mortality in this city is much less than it really is, and that, thanks to the vigilance and ceaseless activity of the Health officials, New York is one of the healthiest cities in the world.

It has been rapeatedly urged by the New York *Herald* that much of the disease and sickness that affects this city is to a very great extent preventable provided the proper means and precautions are adopted.

Until reorganization and change be made in the management of the Department of Health but little improvement can be expected in the sanitary condition of the city, for under the present system no attempt will ever be made to remove the great sources of danger to the public health which exist within the city.

The Health Department should be entirely freed from all political changes and the influence of politicians and run in the interest of the people, and not made a species of medico-political asylum, as it has been in the past. The department should be modelled on the plan of the present Department of Public Works, in so far that it should be placed under one head, to be appointed by the Mayor, and who should hold office as long as his management and the sanitary condition of the city justified. The city should be divided into sanitary or health districts, about fifteen in number, each being placed under the care of a sanitary inspector, who should be appointed by and be responsible to the Health Officer for the condition of his district. The Street Cleaning Department should divide the city into districts to correspond to the health divisions, and the work of street cleaning divided up in this way could be done much cheaper and it need hardly be said in a much better and more satisfactory manner. The sanitary inspector of each district should also be charged with the work of supervising this work, and his weekly certificate that the work has been properly done should be necessary for the contractor to obtain his pay. The clerical force of the department could be materially reduced; also the "contingent" and "stationary" accounts might be made a little less in the future.

One of the greatest evils in the present system is that there is too much division of responsibility, and the health affairs of the city are managed by the chiefs of the different bureaus and not by the Commissioners of Health. One of the special benefits to be derived by a change such as is suggested above would be a concentration of authority and the direct responsibility of the chief officer of health, who should be obliged to devote his entire time and energies to the protection of the public health, and not, as is now the case, every member and attache of the Board having also his own private affairs to look after. By such a system as this, economy and efficiency will be secured, the city will be rendered clean and healthy and over $150,000 will be saved in one department, and can be devoted, if necessary, to the abatement of public nuisances. The badly constructed tenements can be improved with this fund, and the expense, as the law directs, made a lien on the property itself, thus securing the city from any loss and insuring a positive safeguard to the public health.

IMPROVED BOILER FEEDER.

Of the numerous primary points involved in the economical production of steam power, not the least worthy of consideration is that of *feed-water*. In all non-condensing steam engines, the exhaust at every stroke of the piston carries into the atmosphere a large portion of the heat from the boiler, which is thus a source of waste of no mean magnitude. It is obvious, therefore, that any device by which this heat is wholly, or in part, utilized, effects a direct saving of fuel in proportion to the number of heat units returned to the boiler after the steam has performed its duty. Of course a certain percentage of loss from radiation is unavoidable; but, by the proper use of non-condensing jackets upon all exposed surfaces with which the steam comes in contact, the loss from this cause may be rendered so small as to be comparatively inconsiderable. The waste of heat by the exhaust may be briefly illustrated as follows: In boilers for non-condensing engines the ordinary working pressure is 60 lbs. per sq. inch, above atmospheric pressure—the temperature due to which is about 311° Fah. of *sensible heat*. Now, it is clear, that if we exhaust directly from the cylinder into the atmosphere, without making any further use of the steam than the propulsion of the piston, the loss of heat will be 311°, minus the natural temperature of the water used to supply its place—the equivalent heat units of course depending on the volume of steam at above pressure. For instance: If the temperature of the feed-water be 70°, the loss will be 241°, or that number of units of heat contained in the difference between a cubit foot of water at 70° and 383 cubic feet of steam at 311°—In round numbers about 2970 units per cubic foot. If by any device we are enabled to return to the boiler 212° of this heat, the loss will be but 99°, or about 135 units. Thus the saving is 2835 heat units, or 80 per cent. of the previous waste.

These figures being necessarily purely theoretical, must only be taken as an approximation of the practical result, but the comparison, either on practical or theoretical basis, will be found about the same. An apparatus for this purpose (although by no means the pioneer in the field), has recently received the favorable notice

of parties using steam boilers. It combines not only the pump and heater, but also a partial condenser, by means of which all back pressure from the exhaust is removed. The heater actually *does* deliver the feed water at 212°, although doubtless there are many who would be skeptical as to the possibility of attaining such temperature from exhaust steam.—*American Manufacturer.*

TRIP OF CIVIL ENGINEERS TO BONNET CARRE CREVASSE.

MONDAY, *April 30, 1877.*

Upon the invitation of Major Boyd, of the Coast Survey, a number of the members of the Society of Civil Engineers had a delightful excursion up the river to the Bonnet Carre Crevasse. They embarked at Carrollton, accompanied by Professor Forshey, on board the Coast Survey steamer "Baton Rouge," and, through the kindness of the proper authorities, the U. S. Revenue cutter, "John A. Dix," there joined the party, and took the survey boat in tow, thus enabling all to make a quicker trip. The day was lovely, and the plantations with their splendid foliage presented a charming sight, especially to northern eyes fresh from scenes where the snow had so recently whitened the prospect.

Major Boyd had kindly provided an elegant repast, which was enjoyed by all on board shortly before arriving at the Crevasse. Commander McGlensey, of the monitor "Canonicus," and other officers of that vessel, had joined the company at Carrollton, adding, by their geniality, to the general pleasure. The officers of both vessels appeared determined that no attention should be spared that would add to the comfort of the party.

After passing slowly along directly in front of the Crevasse, the party landed a short distance above on the levee, and walked down to the Crevasse, where they observed the river pouring thro' the gap with a velocity of three to four miles an hour, on a length of about a fourth of a mile, having much of the way a depth of over forty feet. This depth, however, does not continue; it soon shoals up to a depth of about eight feet, at the present stage of the river (which is about eleven feet above low water, and within two or three feet of ordinary high water).

Some time was spent in walking along the levee and in examining and discussing the Crevasse. The opinion that it should be closed at the earliest practicable moment, and before the coming of another high river stage, seemed to be universal among the engineers who saw the place and knew its history. The destruction of property caused by this Crevasse has been enormous, and it will increase, unless immediate steps be taken to stop the floods which pass out through this Crevasse. Besides the vast damage to the plantations along the river for long distances above and below, the discharge of such immense volumes of fresh water, loaded with sedimentary matter into Lake Pontchartrain, is injuring the value of that beautiful sheet of water, ruining the property owners around the Lake, and destroying many favorite summer resorts of the people of New Orleans and other places. The loss of so large a body of water, amounting to one-tenth of the entire flow of the Mississippi at that place, must have the effect of shoaling the river just above the head of the passes; so that the people of the whole Mississippi valley have a direct interest in closing this outlet at once.

About four o'clock in the afternoon the company bade good bye, with hearty cheers, to Major Boyd, and returned to the city; everyone expressing the gratification they felt at having the opportunity of seeing this great Crevasse under such favorable auspices.

On the way up the river Major Boyd took occasion to explain very clearly, with the aid of his maps, etc., their methods of surveying by triangulation, and their use of the plane-table in taking the topography.

The whole excursion was particularly enjoyable, and eminently satisfactory to the members of the Society and others of the excursionists.

The revenue cutter landed the party at the foot of Jackson street about six o'clock, where the whole company joined in three hearty cheers for the Captain and officers. Thus ended one of the happiest excursions of the season; and it is hoped that it will bring forth good fruits.

W. M. R.

CORRESPONDENCE.

SHAWANO, WIS., *May 1, 1877.*

EDITOR ENGINEERING NEWS:

SIR.—Allow me to cangratulate you upon your complete success in making the NEWS a *standard first-class* Journal, which must continue to be indispensible to the profession.

A terrible "northeaster" snow storm has just been raging here (on the 28th and 29th ult.) amidst our farming and *log driving* operations. Snow one foot deep with temperature at sunrise 10° F. During the latter part of March five inches of snow fell which enabled the "loggers" to *bank* about one-third of the amount intended.

The log *owners* are now hopeful as the log market will not be glutted as heretofore and good logs will be sure to command better prices.

It has been estimated that Wolf River and its tributaries will raft at the boom fifty millions feet of white pine logs.

Flour is eleven dollars per *barrel*, with a fair prospect for good crop of winter wheat.

President Hayes' conciliatory policy so successful at the *South*, which, together with his honest and economical administration of affairs at Washington has *practically restored confidence*, and business operations will soon resume unusual activity.

"La patience est amere, mais son fruit est doux.

Respectfully yours, J. M.

PROVIDENCE, R. I., *April 25, 1877.*

EDITOR ENGINEERING NEWS:

SIR.—I find two misprints in my last letter, ten 22" sewers instead of two; also 40 acres instead of 400. Please correct the same. I would like some of the readers of your paper who have taken observations upon the flow of water, to give the results as compared with formulæ, or the conditions of result, so that we might be able to compare for ourselves. I found as comparing Neville 140. $\sqrt{RS} - 11\sqrt[3]{RS}$ with a sewer 38"×57" grade, or $\frac{H}{2}$, or $S = \frac{9}{1000}$ and the sewer was 18" deep, the H M R $= \frac{4}{5}$ of .8, or 9.6 inches. Now, the surface velocity was found by experiment, 10 feet per second, taking 4-5ths of this for mean, gives eight feet per second. Neville's formulæ as given, gives 11.70 per second, which is not applicable in this case; but if we take his book upon Hydraulics, page 439, second edition, and take 9 inches as the H M R, we get 8.13 as the velocity; and if we take Molesworth $V = 55\sqrt{x \times 2f}$ per minute, where x = H M R and f = the fall in feet per mile, we get 8 feet per second: and if we take $100\sqrt{RS}$ we get 8.15 feet per second, so that they all three come practically the same. But the last experiment on the 66 inch and this one was make upon sewers, you might say, perfectly smooth, and the results obtained in Providence (I am speaking from experience) would be greater than a great many places I am acquainted with—the main sewers are, as a rule, equal to the best I have seen in England.

I would also wish that some of the engineers who have had considerable experience with the Tidal drains, would contribute to the paper, for I think there is yet a great deal to learn upon this matter. I should say for myself that drains or sewers which are tide locked ought to be calculated from their worst condition, that is, as far as the tide flows in them, for when the tide is up there is no grade, and the only advantage of grade that I can see is, to clean them when the tide is out; what I mean to say is this.—that if a sewer has a grade say 1 in 2000 or 1 in 500, when the tide is out, that the distance the tide flows up the sewer, for that distance it destroys the grade on that section, so that the conditions are, that the sewer in that part is level and should be considered as such when making calculations for the size, etc., or if the sewer is to be trapped or have a tide-gate, then you must consider it has a reservoir for that district below tide level, which I think is a disadvantage in a great many cases.

In answer to J. in April 21st, No. 1.—Some engineers believe in making a step or square fall in the M H where changes in sizes should always come, but I should say, keep the water lines equal; if a curve and a M H at the ends of the curve, make the grade more around the curve for the difference in size. No. 2.—Keep the water lines even but let the lateral drains enter the main sewers so that their water lines are above the general sewage flow for the main sewers, and change at manholes as before stated. No. 3.—Velocity enough to keep clean always, which must be determined according to the specific gravity of sediment.* No. 4.—Hurst says, calculate two-thirds full, and has tables for the sizes, but I should say from the conditions given, having ventilators and free outlets, and the almost impossibility of filling sewers unless too small, that the space is of little account.

W. W.

A NOTABLE RAILROAD RUN.

The unusual run of the fast special train over the L. and N. road Sunday is worthy of something more than a passing notice, as it shows that the condition of the road is not only excellent, but its working organization is practically perfect. The train left here at 8 A. M., with the American Society of Civil Engineers, and made its first stop at Colesburgh, where it arrived *exactly* on time. It then run along to Bacon creek, where it arrived *exactly* on time.

To Bowling Green it then went, where it arrived also exactly on time. Here engines were changed, and on it sped to Nashville, where it arrived on schedule time, and so on with wonderful exactness, to Montgomery, where it arrived at 12:25 A. M., 16 hours and 25 minutes from Louisville, a distance of 490 3-10 miles. Forty-five minutes were consumed for meals along the line of the road.

When it is remembered that the L. and N. is a single track road, with a heavy freight traffic, which was not delayed in the least, and that the average speed of the train in question necessarily had to be over forty miles an hour between stations, it cannot fail to convince every one that the organization of the road is in the hands of the most skillful of men.

The American Society of Civil Engineers is composed of the more talented of their profession gathered from all parts of the country, and these gentlemen of science were very hearty in their commendations of the condition of the track and road-bed that carried them along so smoothly and regularly at so high a rate of speed.

This record of the capacity of the road proves very conclusively that the L. and N. is entitled to the position it holds, that of being a member of the best and most popular route from New York and the cities of the North and West to all parts of the South and Southwest. —*Louisville Courier Journal.*

THE TOPOGRAPHY AND DRAINAGE OF NEW ORLEANS.

BY THOMAS S. HARDEE, CITY SURVEYOR.

The topographical situation of the city of New Orleans is such, on account of its flatness and the proximity to tide level, that the establishment of an efficient and adequate system of drainage has been a problem exceedingly difficult to solve. But an extensive work is now progressing, as shown upon the accompanying diagram, and far advanced towards completion, under a contract with the Mississippi and Mexican Gulf Ship Canal Company, which when completed will revolutionize the present circumscribed system, and it is believed will protect the city effectually from both river and lake overflows, and at the same time simplify and perfect the system of interior drainage for the rapid discharge of all water from the rainfalls and otherwise.

When this work is perfected, an opportunity will then be offered, through more enlarged drainage, to establish a system of underground sewerage, so that the present nuisances of open drains and canals can be abated. This will be effected principally by means of the proposed powerful draining engines, which will be located at the outer limits of the drainage area, and which will be able to reduce the water very considerably below the present inside low water stage, thus creating an additional fall of several feet from the front to the rear more than it now is, increasing the capacity of the outer canal reservoirs, and by this means enabling the bottom or foundations of the present open canals or drains to be lowered, so as to receive the sewerage of the city through permanently constructed covered sewers.

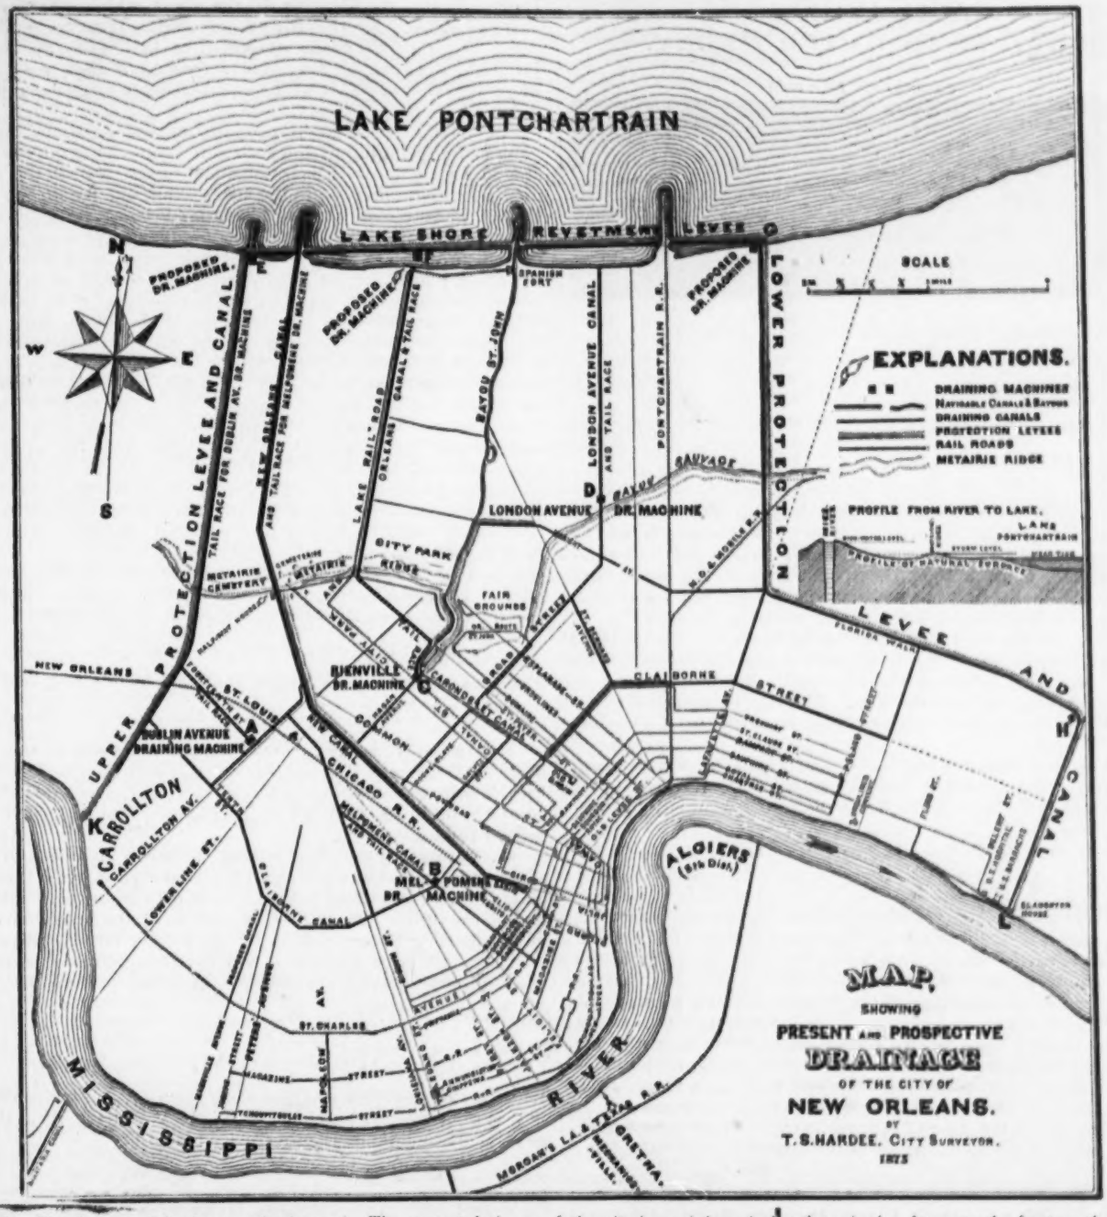
The benefits to the health of the city by the accomplishment of this object alone will be incalculable, and with the combined advantages of protection from overflow and the rapid discharge of all rainfall, there is no reason why New Orleans should not be one of the healthiest and most desirable cities on this continent for a permanent residence. This is certainly a goal to reach, which, if attained by the outlay of millions, will be a trifle as compared to the advantages gained and the benefits bestowed.

The bane of New Orleans as a progressive city has been, that for the want of proper drainage and the evils resulting therefrom, the place has offered but few attractions for the building up and embellishment of homes; and the consequence has been that the bulk of the fortunes which have been made in mercantile pursuits, and which ought to have remained here for investment, have been diverted and taken away to assist in improving other localities more favored by nature in this respect, or which have been redeemed by the successful appliances of art.

The city of New Orleans, with the exception of one district out of seven, known as Algiers, is situated on the east bank of the Mississippi river and this main portion, embraced within the prospective drainage limits, contains about 26,000 acres of superficial area. The city is bounded on the north, or on the side opposite to the Mississippi river, by Lake Ponchartrain, which is an average distance of about five miles from the river. The distance by the course of the river on the front of the city is about 13 miles, and along the shore of Lake Ponchartrain in the rear, the distance is only about five miles. The reason for this apparent inequality is, that the shore line of the lake is comparatively straight, while the course of the river is tortuous.

About half way between the lake and the river there is a natural high ground, called Metairie Ridge, which runs entirely across the city, and which is elevated about four and a half feet above mean tide water. There is a basin or low ground between this ridge and the river, and a flat swampy plateau between the ridge and the lake.

The natural banks of the river on the city front have



been raised uniformly several feet by an embankment commonly designated as the Levee for Protection against river overflow, and the crown of this levee is the most elevated surface of ground within the corporate limits. There is a dish or fall of about five feet in this levee, from the crown to the streets a few blocks distant, so that in the high water season the surface of the river is almost on a level with the heads of the busy pedestrians who ply their vocations in the vicinity.

The water in the river rises and falls about fifteen feet between the extremes of high and low water, and the flood season is confined generally to the months of March, April, May and June.

With the above description, and with the aid of the profile shown upon the diagram, a clear idea can be entertained of the average cross section of the city embraced between the high water of the river and the highest storm level of the lake, showing also the ground intervening between the two which it is necessary to drain and protect.

The fluctuations in the surface of Lake Ponchartrain vary about four feet from the very lowest to the very highest water produced by storms, but the ordinary tidal oscillation is only about eight inches. Owing to these storms, which are periodical, the city has to be guarded against inundations from the lake, in addition to being protected from river crevasses, and hence a combination of difficulties surrounds the question of drainage and protection.

The peculiarity of the water in the river at certain seasons, being so much higher than the adjacent land, renders it necessary that the drainage should be into Lake Pontchartrain, not only as being the natural outlet, but also as offering fewer difficulties than a forced drainage into the river, on account of the difference in elevation, to be overcome in lifting the water.

The present drainage of the city is carried on by means of four draining machines located at A, B, C, and D respectively, as shown upon the diagram. A line connecting the several draining machines will afford a very good idea of the length and extent of the inhabited or built up portion of the city, embracing as it does the space between the river and such a line. These machines each drain a particular section or district of the city, and are located at about the lowest elevation, so that the water which falls upon the slope of each section is conducted by gutters and ditches to the draining point, whence it is lifted by machinery into the level of the lake through the agency of a tail race connecting the draining machine with Lake Pontchartrain. These tail races, which are several miles in length, are formed by a canal about 50 feet wide, the sides of which are strongly leveed for protection against lake overflow, and through them the water level of Lake Pontchartrain is backed up immediately in contact with the draining machines. The tail race forms therefore, a discharging funnel, and the water which falls in each section and collects at the draining machine must pass through this funnel before being distributed into the discharge level of Lake Ponchartrain.

The draining is effected by means of large wheels, with paddles attached similar to an ordinary steamboat wheel, and the revolution of this wheel by steam power, forces a folding iron gate to open, and through this opening the accumulated volume of water is pushed into the tail race, and thus the inside area is relieved.

In connection with the present draining machines there is a continuous back levee as it is called, which keeps even the ordinary tide water of the lake from encroaching upon the low lands in the rear embraced in each section, and this chain of back levees connect with an upper and lower side levee, as well also as the main river levee on the front, so that the entire present limited area drained is walled in by a continuous and connecting embankment of earth. This condition must of necessity exist, owing to the peculiar topographical situation of the city, and the same principle has been adopted for prospective drainage under the enlarged system now being prosecuted by the Mississippi and Mexican Gulf Ship Canal Company.

The *new* and *enlarged* system as contradistinguished from the *present* and *circumscribed* one, is clearly defined upon the diagram.

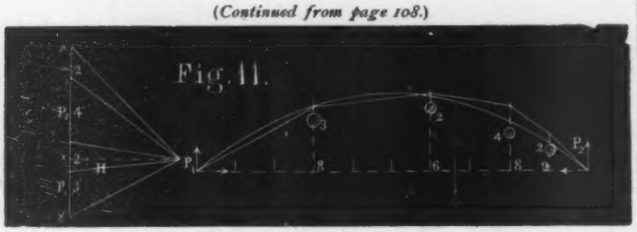
When this new work is completed, the enclosure or embankment wall will then be composed of an upper protection levee from K to E, a lake shore revetment levee from E to G, and a lower protection levee from G via H to L. These three links will form a chain with the already established Mississippi River levee, and will enclose, as before remarked, about 26,000 acres of superficial area. The drainage machines will then be transferred from A, B, C, and D, to the proposed points at E, F, G, and H, and with improved and more powerful machinery will be enabled to relieve effectually every foot of land between the river and the lake.

To be Continued.

T. H. Hamilton, of Toledo, O., who was awarded the contract, on the 20th ult., for the construction of the new dock of the Columbus & Toledo R. R., at Toledo, O., is at present actively engaged upon the preliminary portions of the work with a large force of laborers. The length of the dock is to be 1080 feet x 140 feet, and it is to be completed Aug. 15th next, the expense of the work being about $50,000.

ARCHES;
CONSIDERED GRAPHICALLY.

(*Continued from page 108.*)



$$P_1 = \frac{2\times1+4\times2+2\times4+3\times7}{10} = 3.9 \text{ tons.}$$

$$\therefore P_2 = 7.1 \text{ tons.}$$

From the table for H,

$$H = (0.3176\times3 + 0.372\times2 + 0.232\times4 + 0.1226\times2)\frac{50}{20} = 2.87\times\frac{5}{2} = 7.175 \text{ tons.}$$

These quantities are plotted in the stress diagram, as seen in the figure, and the funicular polygon is then drawn. The reader who reproduces this polygon, or draws another, can be assured of the accuracy of the construction by the closing of the curve of equilibrium on the point of support. The weight of the arch itself may be accounted for by concentrating the proper amount at each point of division, the amounts increasing towards the springing in proportion to the square of the secant of inclination to the horizon; for we recall that the parabolic rib is to increase in breadth from crown to springing, and the amount in length projected into a horizontal foot increases in the same way. The weight of each division of the arch can be obtained with sufficient accuracy from a moderately large figure.

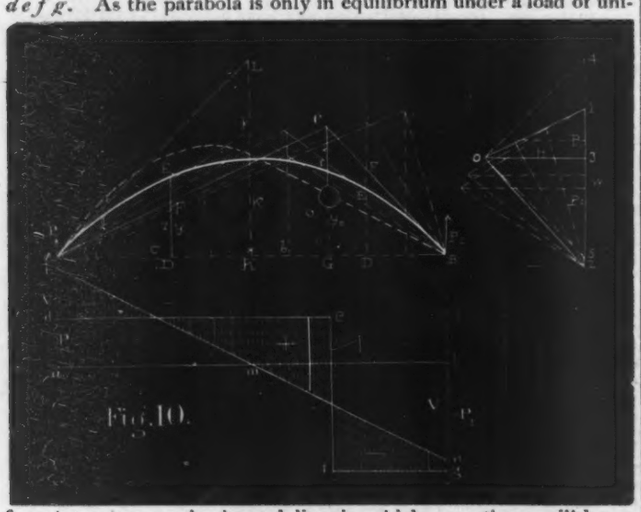
It will be seen that the two curves of Fig. 11 approach quite nearly at 3. We can find the distance between them vertically, if we wish, from the table of M. The bending moment will be, taking the column 6,

$$50\,(+.153\times3 - .073\times2 - .075\times4 - .043\times2) = .3650 \text{ ft. tons.}$$

$$\frac{M}{H} = \frac{.365}{7.2} = .05 \text{ ft.} = y - z.$$

55. It was shown in § 19, where what is meant by *shear* was explained, that it is useful to know the amount and the distribution of the shear at each section; since whatever is not taken up in the flanges or chords of the rib, by being combined with H to give a resultant thrust in the direction of the tangent at each point, must be resisted by the web or bracing. This investigation of shear is intended to apply to ribs of an I section, or to those framed with open-work or skeleton webs, and not to those of solid section, rectangular, circular, or otherwise, nor to stone arches; in these latter classes the shearing forces need seldom be taken into account.

Adhering still to the case of a single weight W, at a distance b from the middle of the span, the vertical component of the reaction, P_2, at the end nearest to the weight will be $\frac{c+b}{2c}$ W, and at the other end $\frac{c-b}{2c}$ W. As seen in Fig. 10, the diagram for total shear wil be, if we take the shear on the *left* of any section, $a\,d = P_1$, on the left of the weight, and $l\,g = -P_2$ on the right of the weight, giving the two rectangles included between $a\,l$ and the broken line $d\,e\,f\,g$. As the parabola is only in equilibrium under a load of uniform intensity on a horizontal line, in which case there will be no bracing required, and therefore no shear for any bracing to resist, it is manifest that the diagram for the shear which is carried, at each vertical section, by the flanges or chords must be similar to the shear diagram for a beam supported at both ends and uniformly loaded, that is, to such a figure as $a\,i\,m\,n\,l$. If then we can determine the value of $a\,i$, or of the equal ordinate $l\,n$, we can draw this diagram.



56. It is a well-known property of the parabola that a tangent at the springing of the arch will intersect the middle ordinate at a distance k above the crown, equal to the rise of the arch. If then we draw a line 0–4 in the stress diagram, parallel to the tangent A L, drawn as just described, the distance 4–3, intercepted on the vertical line, will be the amount of vertical force necessarily combined with H to give a thrust coinciding with the rib at the springing point. Lay off, therefore, 4–3 at $a\,i$ and an equal amount at $l\,n$; then draw the straight line $i\,n$, cutting $a\,l$ at its middle point m; the ordinates to this line from $a\,l$, at all points, will represent the amount of vertical force combined with the horizontal thrust in the flanges. The remainder will be left for the web. The shaded areas represent the remaining ordinates, and, where the amount subtracted by the flanges is greater than the original shear, the remainder will be of the opposite sign. The signs are placed in the areas in the figure, and it will be apparent that the ordinates are practically reckoned from the inclined line $i\,n$, all above that line *on the left of a plane of section*, while those below $i\,n$ will be negative. It is understood that the two flanges or chords have parallel tangents at every right or normal section; otherwise special treatment is required.

57. The calculation of the shear on the bracing is attended with no difficulty. If V = vertical component of the thrust in the rib at any point, we have at the springing, from the statement just made,

$$V_1 : H = 2k : c, \text{ or } V_1 = \frac{2k}{c} H.$$

The shear F on the web, at the abutment on the left, will then be

$$F = P_1 - V_1, = \frac{c\pm b}{2c} W - \frac{2k}{c} H. \qquad (14.)$$

For successive points, P_1 will remain the value of the original shear until we pass the weight, when it will become $P_1 - W$ or $-P_2$. V will diminish at a constant rate, and, if we deduct at each point the ordinate from a l to the inclined line, we shall get the desired results.

58. Let us find the shear *midway* between the points of division of an arch divided into ten equal horizontal parts, for a load on the same point as was taken before, *i. e.*, at 0.4 c from the middle of the span to the right. The load being 3-10ths of the span from one end, the supporting forces will be 0.7 W and 0.3 W respectively. As the shears are to be taken half-way between points of division, the *spaces* are numbered from the left. W comes between the 7th and 8th spaces. $H = .3176\frac{c}{k}$ W.

$$V_1 = \frac{2k}{c} H = 2\times.3176\,W = .6352\,W,$$

the values of the *span and rise disappearing*, and hence this value of V is good for any parabolic arch. If V = .6352 W at the abutment, at the middle of the first space it will be

$$V = (.6352 - \frac{.6352}{10})W = .572\,W,$$

the value placed in the third line at the first space; for every succeeding space V will diminish by $\frac{.635}{5}$ W or .127 W.

VALUES OF F. W.

SPACE 1		2	3	4	5	6	7	8	9	10	
P_1	.3	.3	.3	.3	.3	.3	.3	−.7	−.7	−.7	$-P_2$
V	.572	.445	.318	.191	−.061	−.064	−.191	−.318	−.445	−.572	
P−V.	−.272	−.145	−.018	+.109	+.236	+.364	+.491	+.382	−.255	−.128	W

Thus we get the third line of the table, and P−V gives the desired values of F in the last line. Three decimal places here will be as exact as four in the values of M. If anyone has trouble with signs, an inspection of the shear diagram of Fig. 10 will show where and why they change; the computed quantities are represented by the full lines of the figure.

We repeat again that, because P_1 was taken as positive to commence with, the above table gives the value of the shear on the left side of a vertical section at the middle of each space. In Fig. 12, the sketch marked R is an instance of positive shear on the left of the imaginary section and its accompanying negative and equal shear on the right of the same section. It is therefore evident, from the way in which the two parts of the arch will tend to slide by one another, that, where the shear on the left is upward, or positive, a tie will be required sloping from the upper chord to the right (or a strut in the opposite direction), while negative shear, as represented in the sketch marked S, calls for tie in the reverse direction.

(*To be continued.*)

ARE RESIDENT ENGINEERS NECESSARY?

When those classes of construction known as engineering works are initiated and in progress, the services of members of our profession are usually called for, to see that all parts are executed with due regard to stability, strength and permanent resistance to the elements. In cases where the finished structures are exposed to little deterioration from the lapse of time, the subsequent employment of an engineer is not customary, but where more or less renewal of parts or additional protection is likely to be required it is generally the practice to employ a resident engineer, with such a staff as the extent of the work may render necessary. We find such an officer in the employment of most of those railroads which are of considerable length, and which have difficult and expensive works on their lines. From our own point of view we might say that we find a chief engineer on every well-conducted railroad, for we doubt if a road is long well-conducted without.

We are moved to this line of remarks by noticing that two of the companies which run from Chicago have lately made a move for retrenchment in expenses, by abolishing their engineering departments, and we know of a New England road where the impression is prevalent that, if the chief engineer was not practically discharged, the directors made up their minds that his services might well be dispensed with and he consequently resigned.

In the Western cases above referred to, it is stated that the duties heretofore devolving upon the engineers have been turned over to the division superintendents, subject to the oversight, where required, of a consulting engineer. Our esteemed contemporary, the *Railway Age*, remarks,—"The perfect condition of the road-bed and superstructures, and their permanent character, seem to render this, for the time being, at least, a safe step—as it is certainly an economical one—though the example could hardly be followed with propriety in this country at present, unless, indeed, the division superintendents are themselves competent engineers. It is believed by some that they always should be, and yet a great majority of our most successful superintendents and managers have worked up from the ranks of the operating department, and their acquirements are almost wholly practical rather than theoretical."

Mr. John B. Jervis, C. E., a gentleman past eighty years old, whose engineering experience dates back to 1817, and who has had charge of many and various important works, in a memoir of American Engineering, published in the February number of the current volume of the Transactions of the *American Society of Civil Engineers*, devotes a few paragraphs to the subject of Engineers as Railway Superintendents. His experience in such a position lends weight to his words, and his years will acquit him of egotism. Not to quote more than two or three sentences, he says—"My object is to show that an engineering education fits a man best for the superintendence, no less than for the construction of a railway. I regard it an error that the profession has not given more attention to superintendence of operations. It demands the same thoughtful analyzing mind, to operate, that constructs." "The engineer's education fits him to analyze facts, and, more successfully than a layman, to produce the best results of administration."

If managers and superintendents were engineers, as they are in some cases, and as Mr. Jervis urges that they should be, we might, with an eye to economy, and a due regard to public safety, do away with resident engineers, simply as such. The case is, however, far different, and we cannot but think such a step to be a very short-sighted and ill-advised one.

It would not be a difficult task to pick out a road where the permanent way was in bad order, bridges out of repair, masonry neglected, and things running down generally, not because sufficient money was not spent on repairs, but because lack of intelligent and comprehensive supervision caused it to be wasted. A good resident engineer, after a few years hard work, would systematize the work and the accounts, put material where it is wanted, at the least expense and at the right time, (for we know how, on a permanent way, "a stitch in time" is particularly needed), see to it that the supplies were purchased in season, and not when an inconvenient time gave rise to an increased cost, did not have a quantity of timber or other material stored on one part of the road and then more bought for another place, and, in short, put matters in such trim that they seemed almost to run themselves. Then the directors think that he has little to do, and that his duties can be as well performed by other and probably cheaper labor; they abolish the position, save the few thousand dollars of salary, and apparently all goes well. But unless the charge of these matters has been put into competent hands, which is seldom the case, the permanent way will begin slowly to deteriorate, until the deficiencies become so marked that a new resident engineer is called in. He begins the same up-hill journey of improvement that his predecessor traveled, and the expense to the company is far more in the total than the aggregate of yearly outlay would have been under the old regime.

Doubtless our engineering readers agree with us in these views, so that the expression of them will hardly be of benefit, unless, perchance, they may reach the eye of some railroad officers who are casting about for some way to curtail operating expenses. If so, we would recommend them not to cut off the engineers. We are reminded of cases, somewhat parallel, where municipal corporations have been moved to dispense with the regular services of a civil engineer, calling upon one by the day, or otherwise, whenever they, in their best judgment, thought that he was needed. At other times the work was conducted and repairs made under inferior superintendence. A true balance sheet for the year never showed any economy in dollars and cents, but always the reverse.

We notice that Mr. L. H. Clarke, late the chief engineer of the Illinois Central R. R. has taken a similar position on the Lake Shore and Michigan Southern R. R.

A portion of the roof of the new Post Office in New York fell on May 1. A brick cross-wall which had previously supported a portion of the roof had been cut away and an iron truss had been substituted, timber struts meanwhile having been used to support the superincumbent weight. On the completion of the work and the removal of the timbers, the truss immediately yielded under the load and some 20 feet by 30 feet of the roof fell in, burying four of the laborers in the ruins, and causing the death of three of them. The truss was supposed to be similar to another already in use, and to be as strong. The roof was made of iron beams, carrying arches of corrugated iron, leveled up with concrete and thus protected on the outside with sheets of copper, thus making a fire-proof roof. The concrete was some three inches thick on the crown of the arches, upwards of a foot thick at their springings, and the whole weight is stated to have been 100 pounds per square foot.

As the coroner's jury did not commence their sessions, until Monday, we have not, at the present writing, obtained any information as to the cause of the failure. The jury is composed of four architects and eight practical builders and masons, so that we may hope for a satisfactory explanation of the matter, and will wait for their verdict, in place of giving the surmises and theories of Mr. Mullett or the supervising architect.

CONVENTION OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS.

SECOND DAY.

NEW ORLEANS, *April 25, 1877.*

The meeting was called to order by the Chairman, Prof. Forshey, at 10 A. M.; and after the names of the members and guests who arrived by the morning train were registered, W. Sooy Smith, Chairman of the Committee of Iron and Steel, read the report of that Committe.

After reading the report Gen. Smith gave a brief account of the creation of the Commission on Tests of Iron and Steel, and what it had accomplished. He also alluded to the antagonism of the Ordnance Department and the indifference of Congressmen towards the Commission and its purposes, and in closing he earnestly solicited the co-operation of every member of the Civil Engineering Societies of the country in presenting the subject in its true light and importance to their representatives at Washington. He declared that the Commission could not go a step further without the aid of the society, and the society must work if it would effect anything in time. The time for which the Commission was constituted would terminate this year and therefore if anything was to be done, it must be for the action of next Congress. The speaker in the course of his remarks alluded to Hon. Abram Hewitt in anything but flattering terms, and closed by urging the importance of the subject and that the society in its present meeting take active measures for securing the continuance of the Commission, and the obtaining funds for the prosecution of its experimental labors.

Major Farquhar protested against the attack on the Ordnance Department and remarked that if its side of the story could be heard, it might present a different phase of the question. He also explained that according to the laws of the United States the government funds must be dispensed by its duly commissioned servants.

Clemens Herschel considered it disgraceful that *something* should not result from the money and labor already expended by the Commission, and moved that a committee of three be appointed to draft a series of resolutions to be presented at this convention, such as the exigencies of the case demanded.

The Chair appointed Messrs. Griffin, Bouscaren and Philbrick as that committee.

Mr. Emery hoped that the discussion of the subject would be general, as its importance demanded action prompt and efficient. He remarked that the question is, "Shall the whole matter be put in the hands of the Ordnance Department or shall it be shared with the Civil Engineers Society." There are other than government needs to be considered and it is but a small part of the public works of the country upon which the military engineers are employed.

Government officers consider permanence more than economy in construction and to them the importance of a thorough and accurate knowledge of the qualities of American iron and steel are not so great as to civil engineers who are engaged in bridge building and in other public works throughout the country, and who, while fully realizing the paramount importance of safety and permanence in construction, have also to consider the subject of economy in the use of materials, and who having adopted a sufficient factor of safety did not wish to add to the load by an excess of material. He suggested that an intermediate course be pursued and that the military engineers act as chairmen while the civil engineers take that part in the investigations to which they are justly entitled.

Some further remarks upon the subject were made, and it was suggested that all scientific societies in the country be invited to partake in the discussion, and use their influence in promoting the success of the Commission.

The Chairman announced the programme for Thursday. Gen. G. T. R. Beauregard was then introduced to the Convention and in a neat little speech welcomed his fellow engineers to New Orleans and hoped they would find their visit a very pleasant and profitable one.

E. L. Corthell invited the Convention to visit the jetties at South Pass on Friday. He stated that Capt. Eads, and Mr. Andrews, the contractor, would furnish a steamer for the trip, which would take two days to accomplish, and that the only expense to those going would be for meals while on board. One representative of each of the daily papers of New Orleans was invited to accompany the party to the jetties; the ladies also were invited. A committee consisting of Messrs. DeFuniak, Vaughan and Hardee was appointed to invite others than members of the Convention to visit the jetties with the party, on Friday.

City Surveyor J. E. D'Hemecourt presented to the Society a plan drawn by Gen. Buisson, in 1830, to open a channel from the Mississippi River to the Gulf of Mexico, which would permit vessels drawing 25 feet of water to pass through, which was accepted with the thanks of the Society.

The following was introduced by the committee appointed for the purpose:

WHEREAS, in 1872, a committee was appointed of members of the American Society of Civil Engineers to take into account and to ascertain the best way of establishing a Board for the testing of such metals and alloys thereof as form parts of such structures and machines as are required for the use of this country, and

WHEREAS, in pursuance of such appointment the committee proceeded in their labors, as far as to obtain favorable action from the Congress of the U. S., not only in a law authorizing the creation of a Board for the purpose of making such tests, but also appropriated

money to be expended by said board in the purchase of the necessary machinery, and in the making of such tests, and

WHEREAS, at a late session of Congress a law was passed by which said board would cease to exist on the expenditure of the money thus appropriated, now therefore be it

Resolved, This Society declare the tests proposed to to be made to be of national importance, they therefore ask that so much of the sundry civil appropriation bill passed by Congress, as provides that the board to test iron, steel and other metals, shall be discontinued when the money appropriated for its use by the same shall have been expended, be repealed, and that the unexpended balance in the hands of the board shall be re-appropriated and such other appropriations made for the use of the board as it may require to complete the investigations it has undertaken. The sum required for the coming year being $40,000.

Resolved, That every member of this Society be urged to use such influence as he may possess to obtain favorable and immediate action by the Congress of the U. S. in furtherance of the object here prayed for.

Resolved, That the above resolutions be printed and that each member of this Society be furnished with several copies to be used in furtherance of the object sought and that reports of their action in the premises shall be made by the members to the Secretary, giving the names of each member of Congress as have been seen or addressed on the subject.

E. S. PHILBRICK,
JNO. C. GRIFFIN,
G. BOUSCAREN. } *Committee.*

The Convention then adjourned. At 7 P. M. it was again called to order and the following committee on Nominations was appointed: W. S. Worthen, N. Y.; W. Sooy Smith, Ills.; F. De Funiak, Ky.; J. P. Wilson, Penn.; C. F. Forshey, La.

Prof. Forshey read a paper giving an account of some of his own inventions and patents; some of the former were very remarkable indeed, and when tested we hope to be present.

Mr. Hardee gave a description of a method adopted by him in running a line of levels over the New Orleans and Jackson Railroad, a distance of 400 miles in eleven days, an average of over 36 miles per day, with three negro assistants, and a hand-car.

Mr. Bouscaren illustrated the method of building the Kentucky River Bridge on the Cincinnati Southern Railroad, by means of a diagram on the blackboard. A vote of thanks was tendered to Prof. Forshey for the efficient manner in which he had presided over the meetings. The Convention then adjourned *sine die*.

After the adjournment Capt. Cowden exhibited maps and profiles of the Barrataria Ship Canal and an invitation was given to the members present to accompany Capt. Cowden, free of all expense, over the proposed route of the canal.

THURSDAY, APRIL 26.—THIRD DAY.

At 9 A. M. a large number of the members of the Convention assembled by invitation on board the Underwriters' Iron Fire Boat "Protector," for the double purpose of viewing the levee and water-front of New Orleans, and of inspecting the fire extinguishing apparatus on board the boat. The "Protector" is an iron steamer of 150 tons register, owned by the Board of Underwriters of New Orleans and used solely for purposes of harbor protection. She was built in 1875 by the Harlan and Hollingsworth Company, at their yard upon the Delaware River, and is thoroughly fire-proof. With a 250-horse power engine and a faultless model, she is capable of a rate of speed which is simply astonishing, but is very necessary for her speedy transition to any point along the river front in case of fire. She is provided with most powerful engines for the purpose of throwing water directly upon a fire, in case of such disaster among the steamboats and shipping, and for pumping water into the open gutters, through a 16-inch hose, when a fire occurs on land in neighborhoods into which the pipes of the waterworks do not extend. Besides these, the "Protector" is furnished with the new appliance for forcing carbonic acid gas into a vessel's hold, called the "Carbonic Acid Gas Ship Fire Annihilator," an invention of Capt. A. M. Granger, the energetic and indefatigable agent of the Babcock Fire Extinguisher Co. in New Orleans, who has patented his appliance, and whose zeal in the prevention of loss by fire we hope may be rewarded with commensurate pecuniary success.

Capt. Granger's invention relates to certain improvements in chemical fire-extinguishers, designed more particularly for harbor fire-protection boats and sea-going vessels, but applicable also, in most of its features, to general use.

The general principle of the improvement rests in the direct use of the dry gaseous carbonic acid in smothering volume, in contra-distinction to the common use of a limited quantity of the same dissolved in water under pressure.

The means for carrying out the invention consist generally, in the combination of a set of capacious generators for containing bicarbonate of soda, a set of superposed acid-vessels, a subjacent acid-reservoir, and an air-pump, or equivalent forcing apparatus for charging the acid-vessels from the reservoir, the whole being combined by means of communicating pipes, controlled by valves or cocks, so that the acid may be forced from the reservoir in the hold of the boat only when the effective power of the gas is required, and whereby accidental admixture of the chemicals is, from the motion of the vessel or from other causes, completely avoided.

The apparatus is placed in the stern portion of the vessel just aft of the engine room, and occupies but little space. It consists of three copper tanks, filled with oil of vitriol, each of which connects with lower tanks capacitated for 180 gallons each, which, when exhausted or rather as they exhaust, are refilled from connecting tanks between decks. These lower tanks each contain 448 pounds of bi-carbonate of soda, which is dissolved in water. In front of the tanks connecting pipes run so as to admit of turning them all on at once or separately, as the occasion may require. Attached to and leading into each tank of those between decks is an endless chain, arranged something like a well pump, which is constantly turned while the extinguisher is in operation, thus stirring the soda and water to mix it thoroughly. Every tank is provided with a safety valve and indicator, which, when the cock is turned, permitting the vitriol to descend into the soda water, shows exactly the amount of gas generated. These extinguishers will generate about 60,000 cubic feet of carbonic acid gas, and hence the introduction of this proportion of gas into a space of 400,000 cubic feet of air will more than extinguish any fire, as where 15 per cent. of carbonic acid gas exists, combustion cannot. This apparatus is especially designed for the purpose of extinguishing fire when it occurs in the hold of a vessel where the gas can be confined by battening down hatches.

For fires on deck and in open places, attached to the gas apparatus are two other tanks constructed on the same principle, which, however, throw a strong liquid solution of sulphuric acid and soda.

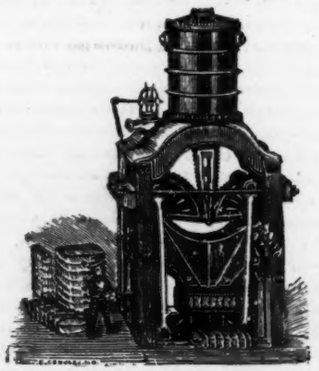
This apparatus has been tested experimentally many times, and has also been put to practical use in saving already some hundreds of thousands of dollars worth of property for its owners, by subduing fires on board three cotton laden vessels in the harbor of New Orleans. There is no doubt that Capt. Granger has effected a revolution in the method of extinguishing fires on shipboard, and we expect to see his apparatus made use of in all the large and crowded harbors of the country before many years more.

The "Protector" steamed first to the Government dredge boat "Essayons," lying on the Algiers side of the river and after a pretty thorough inspection of that "mud stirrer" the party were conveyed rapidly by the gallant tug up the river, past the dry docks, past the long line of river steamboats, and the longer line of sailing vessels and iron steamers lying at the wharves in waiting for cargoes, coming to her landing place just astern the U. S. Coast Survey steamer. While one portion of the company witnessed the working of the Fire Extinguishing Apparatus, of the efficiency of which a most satisfactory test was given by Capt. Granger, another and considerable portion of the crowd had taken most unceremonious possession of the deck of the survey boat, and were being made acquainted with the several appliances for deep sea sounding, testing the temperature of the water at various depths, determining the nature of the bottom, etc., etc., through the politeness of the officers of the survey on board, who addressed themselves at once to the entertainment of their unexpected visitors. After a very pleasant and profitable half hour spent at this point the party, once more on board the "Protector," were taken farther up the river to the works of the Louisiana Ice Company, where they were landed and from whence the tug at once returned to the city.

The extensive works of the Louisiana Ice Co. have been in operation about five years. The ammonia process is used, and the product varies from about 65 tons per diem in the summer time to 84 tons in the winter. In all about 50 men are employed. The ice is produced in slabs 2½ inches thick by 9 inches wide by 24 inches long; a considerable percentage is lost by melting on account of the size of the slabs, but the company were building a machine for pressing the slabs together so as to form cakes of considerable size and thus reduce the wastage. A great deal of interest was taken by all the visitors in the different stages of the conversion of the muddy fluid from the adjacent Mississippi, to the beautiful slabs of pure crystal which about three hours of chemical and mechanical manipulation produced. In another column we have taken the opportunity to publish a portion of the discussion upon a paper read before the Institution of Civil Engineers, upon the "Mechanical Production of Cold," which we thought might be of especial interest at this time to those of our readers who were of the party to the New Orleans Ice Factory. We may observe, before taking our leave of this part of our subject, that the establishment and operation of this factory has reduced the price of ice in New Orleans from $60 per ton to $12, at which it is now selling.

While most of the engineers had been enjoying the sights which we have described, another party under the leadership of Prof. Forshey had been visiting some of the large cotton warehouses for the purpose of seeing the work of the presses. The raw cotton after being subjected to the action of the "gin" is pressed and baled in a loose sort of way at the clumsy wooden plantation presses, and in this shape is delivered on the levee at New Orleans. It is thence hauled to the various improved presses, of which there are several conveniently located near the levee, and after being subjected to the pressure of these ponderous machines, thereby reducing the size of the bale very materially, is ready for shipment to other parts.

We present here an illustration of one of the best styles of cotton press in New Orleans. It is on the Tyler principle, with improvements by a Mr. Morse, of New Orleans, by which fifty per cent. is added to its economy and effective power. We had the pleasure of seeing one of these presses at work, and, so far as we were



able to judge, it seemed hardly possible to improve on the easy and rapid manner with which it performed its ponderous work. Mr. Morse claims for his invention, that the shape of the rack and sections as shown in the cut, gives a progressive and immense leverage so that nine powers are practically attained, enabling the press to do better work with 80 pounds of steam pressure than others with 120, thus saving ten to fifteen dollars in full per day. It has a capacity of 75 to 100 bales per hour, which at 75 cents per bale ought to yield a very fair profit to the factor.

From the ice factory the united parties proceeded by horse cars to the city terminus of the Carrolton railway, where they were hauled by the well known fireless locomotive to Carrollton, a distance of about three miles. At this point the party witnessed the charging of the locomotive with superheated steam, and also visited the levee close by, where Prof. Forshey, who is supposed to know "all about levees and the Mississippi river generally," gave the party the benefit of his familiar acquaintance with the great "Father of Waters." Having disposed of very nearly the entire stock in trade of the solitary vender of fruit, pies, and villainous fluids, at the Carrolton depot, the majority of the party betook themselves to the *elegant* vehicles which had been provided for their transportation to the drainage works, cemete-

ries and such other points of interest as the programme had specified, and from whence they returned to their hotel with the conviction that the ancient city of New Orleans needed drainage, sewerage, water-works, and public works generally, and that evidently there was work for civil engineers to do there before many years.

A special train landed the party at the Lake Pontchartrain hotel shortly after 7 P. M., and the continuous journeying of the entire day not having whetted their appetites sufficiently the whole company strolled leisurely down the half mile wooden causeway to the lake, looked at the light-house, speculated upon the length, breadth, depth, height, flavor, and other qualities of Lake Pontchartrain, and then strolled back again to dispose of that part of the programme entitled the "Convention Dinner." About 75 persons, ladies and gentlemen, sat down to the tables, which were well arranged and tastefully decorated with a profusion of flowers. New Orleans is noted as a fish market and the bill of fare of this banquet was largely of fish. Everything connected with the evening's entertainment was in most excellent taste and reflected great credit upon the committee who had charge of the matter. Engineers are not noted as after-dinner speech makers, and so we shall not attempt to reproduce the wit and wisdom of this happy occasion. The train took the party to the city at 11 P. M., and we do not well see how there could have been any headaches the next morning from the effects of the evening's hilarity.

The grand excursion of the occasion—the trip to the jetties at South Pass—left New Orleans the next morning at 10 o'clock, and next week we propose to give our readers a full account of that most delightful journey.

ON THE MECHANICAL PRODUCTION OF COLD.*

BY ALEXANDER CARNEGIE KIRK, ASSOC. INST. C. E.

By the mechanical production of cold as distinguished from cooling by radiation or conduction, the author would in the following paper, be understood to mean the removal of heat from a body by a continuous circle of mechanical operations, without the use of anything colder than the body it is desired to cool. He will chiefly confine himself to a description of apparatus, in which the medium used is an incondensable gas such as atmospheric air.

Every machine for producing cold, under the conditions stated, is simply the negative solution of a motive-power heat-engine. A motive-power heat-engine absorbs heat at a high temperature, rejects it at a lower temperature, and develops an amount of power in proportion to the number of degrees through which the temperature falls. A machine producing cold is such an engine, absorbing heat at a low temperature rejecting it at a higher temperature, and requiring work to be spent in driving it in proportion to the number of degrees through which the temperature is raised. Heat in falling from a high temperature to a lower temperature exerts "work;" and "work" has to be expended to raise a low temperature to a higher temperature. The thermo-dynamic formulæ for every heat engine apply equally to the corresponding refrigerating machine; the work in the former appearing as a positive, and in the latter as a negative quantity. It is a condition, equally of a motive-power engine and of a refrigerating machine, that the temperature at which heat is rejected should be high enough to be abstracted by surrounding bodies—in practice water; and thus this temperature is much higher in tropical countries than at home. The most familiar motive power engine, the steam engine in its most complete form, becomes a refrigerating machine, the water in the boiler being evaporated nearly in vacuo, and condensed at something over the atmospheric pressure. Harrison's well-known ether machine is the same; ether being substituted for water on account of its lower evaporating point, by which temperatures as low as zero in the Fahrenheit scale can be reached. This may serve as an illustration of machines for cooling purposes in which condensable vapor is used.

Similarly, any engine, such as Ericcson's air engine, or Stirling's, using an incondensable gas may become a refrigerating machine; expansion by heat and compression combined with cooling serving the same purpose as evaporation and condensation in the former case. The first has been often tried as a practicable refrigerator.

* Paper read before the Institution of Civil Engineers, London.

[The paper is a long one and being illustrated cannot at present be reproduced in full by us; we therefore quote only some parts of the discussion which followed its reading.]

Mr. Siemens said if he wished to be critical he might find fault with the title of the paper. The author spoke of a machine for "the production of cold." Cold was the absence of heat, and it might be open to question whether it was possible to produce the absence of a thing. Refrigeration, which he thought the preferable word, meant the transfer of heat from one substance to another of the same or a superior degree of temperature, and the author evidently agreed in that definition. The subject was one of considerable interest at the present time. Refrigerating machines were now largely used in breweries, since fermentation went on to advantage only at a temperature a little above freezing point; and to attain that point during all seasons of the year rendered artificial means of maintaining a low temperature necessary, unless native ice was employed for the purpose. For preserving meats also in hot climates and transporting it, artificial means of reducing the temperature were coming into use, and would be more extensively employed if a cheap and ready method could be devised. Refrigeration was of great importance in hot climates in a sanitary point of view, and the time was not distant, he thought, when houses and places of public resort would be refrigerated with the same care and regularity as they were now heated when necessary. He believed this might be accomplished at a cheap rate. It was stated in the paper, and it was an undoubted scientific fact, that mechanical refrigeration might be obtained at a cheaper rate if the reduction of temperature required were only slight than if it were considerable. Thus, an air-machine producing ice would work much less economically than one producing only cool air. In order that the subject might be more fully opened out for discussion, he proposed to refer shortly to the different methods that had been devised for producing refrigeration. There were four methods in use. The first was the old system by the evaporation of alcohol, ether, or other volatile substances. Even water when allowed to evaporate under a current of air produced refrigeration. Alcohol did so to a greater extent, and ether to a still greater extent. This method had been adopted, perhaps for centuries; but in recent times it had been improved by Siebe and by Harrison, who had contrived that the vapor produced by evaporation should not be lost, but that it should be mechanically compressed and condensed, in order to serve over and over again. The method of producing the reduced temperature was the same in both cases, but instead of losing the ether or alcohol, a certain amount of power was expended in the improved arrangement. Another method was the chemical one of producing refrigeration by evaporation in connection with absorption. Many vapors—ammonia being one of them—were readily absorbed by water, but could be separated again by the application of heat to the mixed liquid. A machine on that principle was shown at the Universal Exhibition, in 1851, by M. Carre, and very good results had been realized by it. It consisted of a boiler which was filled with ammoniacal liquor, and the ammonia vapor was driven off under considerable pressure into a surface condenser composed of tubes surrounded by cool water. A separation was thus effected by heat of the ammonia from the water; and the ammonia, after being withdrawn into a vessel of lower pressure, evaporated at a very low temperature, and thus produced refrigeration, the vapors of ammonia being eagerly absorbed by water of ordinary temperature forming mother liquid for re-evaporation in the boiler. The machine was largely used, especially on the Continent; and, from information he had received, it produced a hundredweight of ice at the expense of about a shilling. An ingenious modification of this machine for small applications on board ship or for household use had been devised, consisting of two vessels connected by a pipe, but hermetically sealed. One of the vessels contained the mother liquid, which was alternately heated and cooled, to drive off the ammonia, and to re-absorb it from the second vessel, which served alternately as condenser and refrigerator for the production of ice. Another method was by the solution of crystalline substances. There were various refrigerating mixtures, one of the salts so employed being carbonate of ammonia, and another chloride of calcium. When crystals of chloride of calcium were dissolved in water, a considerable reduction of temperature—about 30° Fahrenheit—took place. Although that would not be sufficient to produce ice from water of 60° or 65° temperature, an arrangement could be made by which the water to be cooled exchanged heat with the spent liquor, thus producing an accumulation of the effect in the center of the machine. He constructed a machine on this principle many years ago, which produced ice at a considerable rate, but the salt employed—chloride of calcium—was not a pleasant substance to deal with. It had to be re-evaporated and crystallised, and this process was inferior to the purely mechanical methods which had since been adopted. The most perfect of these, as regarded cleanliness and freedom from loss, was the air machine. Atmospheric air was compressed to one-half or one atmosphere above atmospheric pressure. The compressed air was allowed to cool in contact with water, either by external application or by injection, and to expand again in a working cylinder. The amount of heat that disappeared in the second working cylinder was the exact measure of the refrigeration produced, and it could be easily calculated; whereas the power expended was the difference of force involved in compressing the air at a higher and of expanding it at a lower temperature. In 1857 a machine of that description was invented by Dr. Gorrie, an American, and was brought to London. Mr. Siemens was asked to report upon it. The machine did not produce satisfactory results. The engine was a good one, and the air-pump was judiciously constructed; but the connection between the reservoir containing the compressed air and the air-expansion engine was too narrow, and was provided with a throttle valve, there being evidently a vague idea in the mind of the inventor that the air would produce more refrigeration in expanding spontaneously without doing work than in expanding behind a working piston, an idea which was permissible at that time when the dynamical theory of heat was little understood. That was one of the defects which he pointed out. Another was that the hot or compressed air was not sufficiently cooled before it was expanded, and was not deprived of its moisture. The moisture in air played a considerable part in those machines. At a temperature of 65° Fahrenheit saturated air contained 1 per cent. of vapor of water, and this had not only to be reduced into the liquid, but also into the solid condition representing a total absorption of heat to the amount of 1,140 units of heat per lb. of condensed vapor, which upon the quantity of air, would represent 15° Fahrenheit of loss in the effect produced by the expansion. He believed, if these faults had been remedied, the machine would have given satisfactory results. Since that time a German engineer, Mr. Windhausen, had constructed machines on similar principles, and had, after many fruitless attempts, obtained remarkable results. It was stated, at a meeting in connection with the Vienna Exhibition, that a machine of 150 H P. produced 30 cwt. of ice per hour, the theoretical result being that that amount ought to be produced by 90 H P. The cost of producing a hundredweight of ice by this machine was stated to be one shilling—a similar result to that obtained in M. Carre's machine. The machine described by the author of the paper was also an air machine, a reversed air-engine, so to speak, and therefore, in a certain sense, analogous to those he had before mentioned. The author did not compress the air, cool it, and then transfer it into a separate cylinder to be re-expanded, but he combined these operations in an engine similar, in every way, to Stirling's air-engine, on a supposition that that was the most perfect air-engine known, and that, in inverting it, he would be likely to obtain the best result of refrigeration. He could not, however, agree in the opinion that the Stirling engine was a perfect one. It was the first engine containing a regenerator; but (as he had pointed out in a paper read before the Institution in 1853) it realized, at most, only from one-fifth to one-sixth part of the theoretical duty of the heat expended. The reason was that all the air cooled and heated alternately, did not enter the working cylinder; but the diagram of the force obtained in the working cylinder formed only a sixth part of the diagram that would be produced if the whole of the air were allowed to expand behind a working piston and between the same limits; and that proportion really indicated the dynamic value of the engine.

Therefore, although he admired the ingenuity with which the author had enlarged the available heating surfaces of Sterling's arrangement, and elaborated the best form of regenerator for the purpose, he could not agree in the application of that principle to refrigeration. He believed better results would have been obtained if the compression apparatus had been separated from the expanding apparatus as had been done by others. That opinion appeared to be corroborated by the results given in the paper. With 37 HP. twenty gallons of water were reduced from 61° to 47¼° per minute, which was equal to 2.8 lbs. of ice per hour, whereas the Windhausen engine was said to produce 20 lbs. of ice with 1 HP. Generally speaking, he believed the air-compression engine, on the purely mechanical mode of producing refrigeration, was applicable with the greatest advantage where moderate refrigeration was required. Where the production of ice in large masses was desired, he believed the method adopted by Siebe and by Harrison was superior, for this reason: in compressing and produce the effect of 1 lb. of ice; whereas in compress-expanding air, 25,000 cubic feet of air were required to ing sulphuric ether after evaporation, only 5,100 cubic feet were required, the reason being that when sulphuric ether was transferred from the liquid into the gaseous condition, the whole of the latent heat was obtained. A much higher result was arrived at by using a still more volatile substance—methylic ether—which at a depression of temperature equal to 15° Centigrade had a pressure of 1½ atmosphere, and the displacement of piston to produce the same effect was only about 340 cubic feet. Therefore a pumping engine, with a displacing capacity of piston of 340 cubic feet per minute, would produce the same effect as an air engine of 25,000 cubic feet displacement per minute, and of 5,000 cubic feet in the case of a sulphuric-ether engine. This meant a much smaller engine and a less costly machine in the case of the methylic ether pump, although the expenditure of power might be the same; but on the other hand, there was the set-off of having to deal with a highly inflammable material like methylic ether instead of with atmospheric air. For producing a depression of temperature in houses or breweries he believed the air-engine was the best contrivance that could be adopted.

Mr. Rees Reece said the machine devised by the Author was the most complete one of its class yet constructed; but he now came to another method of applying cold, independent of mechanical power. All that was required was to burn a given quantity of coal under a steam boiler, and the energy produced by that coal was the whole energy required. Mr. Philip Ferdinand Carre, fourteen or fifteen years ago, when engaged in the construction of ether machines, finding it difficult to carry them through, was led, after some researches of M. Regnault, to construct an ammonia machine. Mr. Carre took a quantity of strong solution of ammonia, and boiled it over and into a condenser. He found, as others had done since, that 100 lbs. of strong solution of ammonia, boiled by a distillation up to 5 per cent., yielded 75 per cent. of ammonia, and 25 per cent. of water. This being condensed would be used effectively for refrigerating purposes. The only drawback was that the liquor condensed contained 25 per cent. of water, and holding a large quantity of ammonia made the machine intermittent and relatively costly, but not nearly so costly as an air or ether machine as a method of producing cold. The French Academy appointed a commission to investigate the subject, and that commission pointed out the want of complete success in the machine, stating that what was required was a method by which ammonia could be had nearly anhydrous on one side, and an exhaust liquor on the other free from ammonia. This led him to study the problem, and he would briefly state what he had done. By mixing two liquids together of different boiling points, one liquid could be separated thoroughly and perfectly from the other. When alcohol was mixed with water up to 5, 10, or 20 per cent., by a process of fractionation, the two could be separated; and it occurred to him that he could thoroughly remove the whole of the water contained in the mixture, and obtain on one side of the instrument ammonia free from water, and on the other side water comparatively free from ammonia. This he had been enabled to do, and the ammonia obtained in this way, passing through a condenser without the aid of any mechanical energy, was condensed simply by its own accumulation, and a current of cold water passing round it. Passing that ammonia into a refrigerator, he connected it to an absorbing vessel containing water or exhaust liquor; and simply opening a cock connecting them was sufficient for it to resume its aeriform condition, without the aid of any mechanical force, the gas being removed by its solution in the liquor of the absorbing vessel. In the case of the ammonia, the same as the ether, a portion of the work of the refrigerator was to reduce the temperature of the ammonia from that of the condenser to that of the refrigerator at its working temperature. Instead, as in the case of the ether, using from 14 per cent. to 30 per cent., he found, in reducing it to 41° he had used 2½ per cent., in reducing it to 14° 4 per cent., to zero 5 per cent. For every lb. of ammonia thus liquefied in the liquefactor, 920° of heat were given out, *i. e.*, it heated 920 lbs. of water through 1°. In the evaporation of the same quantity of ammonia it cooled down 920 lbs. of water through 1°. At whatever temperature it worked the cost of refrigeration was the same; by means of ammonia, therefore, cold could be produced at the cheapest possible rate. The relation existing between ammonia and ether was the relation between 168 and 920, irrespective of the mechanical energy required. There was one other advantage in the use of ammonia. When the temperature of the cooling cylinder was reduced 30 below zero, it had still a mechanical energy and force equal to that of water at 212, and going down further, 10, 15, 20, 30, 40, 50, and even a temperature of 60 degrees below zero of Fahr, it would be as energetic an instrument as at any higher temperature, whilst all others deteriorated in efficiency as the temperature fell. Taking a pound of coal and burning it clean under the same boiler, 8,500 heat units would be transmitted to the water. Using that to work a good air machine, 200° of heat would be absorbed; in the ether machine, 600°; in the ammonia machine, 4,000°. These differences showed the real economy of the different systems. It was essential that the machines, whatever system was adopted should be well constructed. * * * * *

Mr. Bourne observed that it would be an invidious task to pronounce upon the rival pretensions of the different freezing machines of which the characteristic features had been expounded; but it might not be inopportune to offer a few general remarks on the subject of refrigeration.

Cold was produced by radiation into space, by the liquefaction of solids, by the vaporisation of liquids, by the dilatation of gases, and by electricity.

In the upper provinces of India ice was obtained by exposing water, in shallow porous vessels, to the cooling influence of the sky during clear nights. The evaporation from the porous vessels cooled down the water, and the radiation of heat from the surface produced a film of ice, which in the morning was skimmed off and preserved for use. It was a necessary precaution to place the vessels upon a layer of straw, so that they might not be affected by radiation or conduction upward from the earth; and it was also indispensable that the sky should be free from clouds, else the heat was radiated back from the clouds, and freezing did not take place. The operation of the same laws occurred in the deposition of dew. The surface of the earth was cooled by radiation, and the moisture of the air was condensed by the cold surface and precipitated as dew, in the same way in which moisture was precipitated upon the surface of a glass of cold water in summer, or upon the windows of a heated room when the air outside was cold.

If ice at 32° was heated over a fire, it would take some time to melt, although it had all the while been receiving heat, and although the resulting water was still only at a temperature of 32°. This showed that melting absorbed heat; and when the heat was supplied from any extraneous source the liquefaction was a source of cold. Thus when certain salts were melted in water cold was produced, and those salts were called freezing mixtures. So also a low temperature resulted when snow and salt were melted by being mixed together.

The vaporisation of liquids was one of the usual ways of producing cold. In India water was cooled by pouring it into a metal bottle, which was then wrapped in a wet cloth and swung in the sun. The heat and current of air induced rapid evaporation, which cooled the contained water. When the hot winds prevailed in the arid parts of India, houses were cooled by blowing air through a thick matting kept constantly wetted with water. The evaporation of the water cooled down the air to an agreeable temperature, and the hotter the wind the greater was its avidity for moisture, and the greater the refrigeration.

The dilatation of gas, as well as the evaporisation of liquids, afforded a powerful refrigerating agent, and one or both of these expedients was called into play in the different freezing machines. In Mr. Kirk's machine atmospheric air was the gas employed. The air was compressed by a piston, by which means the temperature was raised, as in the syringe for lighting amadou tinder by the sudden compression of air. The heated air was cooled by water, and was then suffered to expand, when it sought to recover from surrounding objects the heat it had lost, and thus lowered their temperature.

Electricity was a source of cold not yet developed, but which appeared worthy of attention. More than thirty years ago Peltier, in experimenting on the thermo-electric battery, discovered that cold was produced by a current passing from the bismuth to the antimony. All the freezing machines described in the course of the discussion were virtually thermo-dynamic engines inverted. Such engines uniformly worked with a great loss of effect; and the efficiency of electro-magnetic engines was about four times greater than that of heat engines. A similar relation might, perhaps, hold in the inverted machines.

In all thermo-dynamic machines there must be two temperatures, just as in the generation of power by gravity there must be two levels, and in the subsidence of the weight from the higher to the lower level power was generated. In freezing machines there was only one temperature to begin with, and that had to be raised at one end of the machine, or to be depressed at the other end, by an expenditure of power, just as power had to be expended in winding up a weight. It was a law of thermo-dynamics, that the same quantity of heat, with the same extremes of temperature, would generate the same amount of power, whatever might be the medium through which the heat was made to operate—whether it was steam, or air, or water, or metal, or any other substance. The converse of this proposition would also be true; and just as a given expenditure of heat would produce a corresponding amount of power, so would a given expenditure of power produce a corresponding amount of refrigeration. Excluding details, therefore, and without entering into minutæ, there was no theoretical reason why one freezing machine should not be as efficacious as another. The difference between them was not so much a difference in principle as a difference in cost, or convenience, or safety or something of that nature. As heretofore constructed, the air machine appeared to absorb more power to do the same work than some others; but this result he considered accidental to the mode of construction adopted, and that it might be obviated in future examples. If, in point of cost, all the systems were made equal—which he believed to be the inevitable tendency—then the question of comparative merit would narrow itself to considerations of safety and convenience. He could not assent to the remarks of one of the constructors of ether machines, as to the visionary nature of the apprehensions entertained in regard to the danger of ether, especially on board ship. A system of supplementing the power of steamers by the employment of ether was, some years ago, proposed by M. Du Trembly, and this system was applied to several steamers by the late Mr. J. W. Jameson, Assoc. Inst. C. E., who had read a paper on the subject before this Institution, and who had referred to some of the accidents that had occurred. He did not maintain that the risks of using ether in freezing machines on shore were as great as those arising from its use in engine-rooms at sea; but he thought that all vapors, like those of ether or ammonia, which were inflammable or poisonous, and liable to leakage under high pressures, were objectionable on shipboard, whereas atmospheric air was harmless. He believed, too, it was on board ship that one of the most valuable applications of the freezing machines would yet be found—in enabling frozen meat to be brought from all parts of the world in vessels specially constructed for its conveyance.

THE TOPOGRAPHY AND DRAINAGE OF NEW ORLEANS.

BY THOMAS S. HARDEE, CITY SURVEYOR.

(Concluded from page 114.)

One difficulty about the location of the present draining machine is, that they are near the inhabited portions of the city, and with so little fall in the drains leading to them as at present constructed, that after a heavy rain-fall, and before the machine can be set in motion, the closed gates of the draining machines, together with their side levee, form such a dam or barrier, that the tendency must be to back the accumulating water far up into the front limits of the city before relief can be obtained.

An additional difficulty, too, which now practically exists, and which contributes more than anything else to delay the proper relief, is the want of capacity in the present street gutters and other drains for conducting the water fast enough to the main drainage or reservoir canals. Owing to these combined difficulties, it is not infrequently the case during a heavy rain that on some of the most populous thoroughfares, people are kept waiting for hours before being able to cross the streets.

By the transfer of the draining machines to the points designated, these difficulties must be provided for and can be overcome, and the inferior dam or barrier alluded to will have a substitute in the lake shore revetment levee, which being so remote, and having behind it so extensive a reservoir as contemplated, will offer no obstruction whatever to the free and rapid outflow of all water from the front. By this new system, also, the use of long tail races will be abolished, and the water will be forced by simpler process at E, F, and G immediately through the revetment levee into the lake, and at H through the protection levee into the adjacent swamp. By the present system the machinery is unduly taxed to wash the inside water through a long column represented in volume by the cross section and length of the tail race, and this too before the water to be discharged can reach the distributing surface or level of the lake.

The lake shore revetment levee, a part of which is completed, will be made from the excavations of a canal about twenty feet deep and sixty feet wide, and as it is located several hundred yards from the lake shore, where the water is about three feet deep, it will be readily conceived what an extensive basin or reservoir this canal and surroundings will afford for the reception of water.

It is expected that the new draining machines in the interim between rains will keep the surface water in the contiguous canals reduced to a point six or eight feet lower than what it now is relatively at the present draining machines, and this will, of course, greatly increase the plane of inclination of all interior canals leading thereto, and consequently augment the flow of water to the points of drainage. When this result is accomplished, it will follow that a system of underground sewerage can be successfully established, which will abate the present nuisance of open drains and canals, and thus wonderfully improve the sanitary condition of the city.

As an adjunct of this system of underground sewerage, and as a valuable auxiliary to the general plan of sanitary improvement, it can easily be arranged for the water of the Mississippi river during at least three months of the year, when it is in the neighborhood of flood height, to be conveyed by iron pipes through the levee on the river front into every street, and thus keep the gutters and sewers thoroughly washed and cleansed at a season of the year when it is most needed. The iron pipes for this purpose can be constructed with an adjustable gate, so that when the water is not needed during a rainy period it can be cut off, and when the gate is opened the water will flow of its own accord, as long as it is within four or five feet of highwater mark. The period of the year when the water would thus flow from the river would be generally from the 1st of April to the 1st of July.

The value and importance then of this improvement, as a means of sanitary reform, can scarcely be overestimated, and it seems as if nature had placed within our reach one great compensating advantage for the many other disadvantages with which she has surrounded us.

In view of the advanced stage of the work now being prosecuted by the dredge boats of the Mississippi and Mexican Gulf Ship Canal Company, it is idle to discuss for the present the feasibility or better adaptation of any other plan for the drainage redemption of New Orleans There has already been expended the sum of about two millions of dollars upon the work, and it is now about one half completed. All of the suggestions, therefore, which have been made in this paper have been based upon the presumed successful completion of this work. One great practical advantage which has already been achieved by it exists in the upper line protective levee, as shown upon the diagram, and which is finished in a substantial manner from the river to the lake. It happened that in 1849 the level broke at a point about fifteen miles above the city, and caused what is historically known in Louisiana as the Sauve Crevasse. The water from the break swept like a deluge upon the city, and for several months navigation in skiffs and canoes through the principal thoroughfares was the order of the day, causing a vast amount of inconvenience and damage,

The situation to-day is, that if a similar crevasse should occur, or a serious break in the levee take place at any point above the limits of the city, this upper line protection levee would act as such a barrier that no calamity like that of 1849 could ever with reasonable expectations happen again.

This levee, together with the lake shore revetment levee and the lower line protection levee, are being constructed from fifty to sixty feet wide on top, and from four to six feet above the highest water known, and are so arranged in their top cross sections that a shell road and a double car track will be afforded entirely around the city from K to L, a distance of about seventeen miles—thus promising a degree of utility with pleasure seldom combined e sewhere in a work of such vast public importance.

The future of New Orleans, as a great and populous city, depends more upon the successful solution of this drainage problem than almost any other question connected with her welfare. Give us the energy, the public spirit and the means to carry out this promised protection from overflow, combined with an efficient system of interior drainage, as herein marked out and with healthfulness thereby established, together with returning commercial prosperity, we will be enabled at no distant day to have our city extended through the present swamps to the shores of the lake, with beautiful homes occupying every foot of space within her limits, and capable too of maintaining a population of more than a million of people.

CO-ORDINATE SURVEYING.*

BY HENRY F. WALLING, C. E.

Concluded from page 112.

In this first case, the old co-ordinates of the new origin are, accordingly, positive while the new co-ordinates of the old origin are negative. Or, if we call the old co-ordinates a and b, and the new ones a' and b', a and b are here positive and a' and b' negative.

2d. When the new origin is west and north of the old, or a negative, b positive, a' positive and b' negative.

3d. When the new origin is west and south of the old, or a and b negative, and a' and b' positive.

4th. When the new origin is east and south of the old, or a positive, b negative, a' negative and b' positive.

For ascertaining the new co-ordinates of the old origin, the equations—

$$-a' = a \cos.\ \varphi + b \sin.\ \varphi,$$
$$-b' = b \cos.\ \varphi - a \sin.\ \varphi,$$

would prove correct in all these cases, provided proper positive and negative values were given to the different terms in the equations. It is necessary to remember, however, that φ, the angle of change in direction, between the old and new axes, is positive according to trigonometrical usage when reckoned from zero around towards the left, and negative in the opposite direction, while according to the geodetic method of estimating azimuths, positive angles are reckoned around to the right.

To avoid the confusion which might arise from these different methods of estimating angles, or from assigning a negative value to φ, equations are given below for each of the four cases. Their correctness will be apparent on simple inspection of the accompanying figures, in which O and N are the old and new origins respectively:

CASE FIRST.

$$a' = a \cos.\ \varphi \quad b \sin.\ \varphi,$$
$$b' = b \cos.\ \varphi - a \sin.\ \varphi.$$

CASE SECOND.

$$a' = a \cos.\ \varphi + b \sin.\ \varphi,$$
$$b' = b \cos.\ \varphi - a \sin.\ \varphi.$$

CASE THIRD.

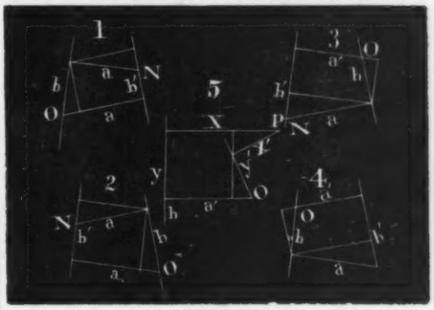
$$a' = a \cos.\ \varphi - b \sin.\ \varphi,$$
$$b' = b \cos.\ \varphi + a \sin.\ \varphi.$$

CASE FOURTH.

$$a' = a \cos.\ \varphi - b \sin.\ \varphi,$$
$$a' = b' \cos.\ \varphi + a \sin.\ \varphi.$$

In these equations the negative sign is omitted before a' and b', but we must remember that they are always estimated in directions opposite to those of a and b.

Since φ is a very small angle, *cos.* φ approximates closely to unity, and it appears by these equations that



a' is greater than a, and b' is less than b when the new origin is farther *north* than the old, while a' is less than a, and b' greater than b when the new origin is farther *south* than the old.

Having found the new ordinates of the old origin, that is of O referred to N, the ordinates of any point referred to the new origin may be computed from its old ordinates by the equations:

$$x = x' \cos.\ \varphi - y' \sin.\ \varphi + a$$
$$y = x' \sin.\ \varphi + y' \cos.\ \varphi + b;$$

in which x = departure of any point as referred to N,
x' = departure of the same point as referred to O,
y = difference in latitude of any point as red to N,
y' = difference in latitude of the same point as referred to O,
a = departure of the origin of O as referred to N,
b = difference in latitude of the origin of O as referred to N,
φ = the angle of convergence of the meridional axes of N and O.

These are the formulæ for passing from one system of rectangular co-ordinates to another in the same plane.

In these equations, we may consider north and east to be the positive directions as before, the opposite directions being negative. Also *sin.* φ is positive when the change of axial direction is towards the left, and negative when in the opposite direction; that is, positive when N is farther east than O, and negative when farther west. *Cos.* φ will always be positive, since φ is always either in the first or fourth quadrants.

In Fig. 5, the point P, of which x and y are the new co-ordinates, is east and north of the axes passing through O, making x and y greater than a and b respectively, and all the terms of both equations have, accordingly, positive values. But if x, x' or a be estimated towards the west, its sign must be reversed when particular values are substituted in the equations; likewise, if y, y' or b, have a southern direction, its sign must be reversed;

CO-ORDINATES IN A SINGLE DISTRICT.

It is hardly necessary to say that when the azimuth and distance are given from a point whose co-ordinates are known to any other point, the co-ordinates of the latter are found by multiplying the given distance by the sine and co-sine of the azimuth, the first product giving the departure and the other the difference of latitude.

VERIFICATIONS.

Before finally establishing the co-ordinates of a survey its accuracy should be tested in the most rigid manner, both as regards the instrumental observations and

the computations. The computations are easily verified by working to the same point from different directions.

COMPUTATION OF AREAS.

Areas are computed under this system with special facility and certainty, the method being the common one of double latitudes and departures. This method is prescribed by law in the State of Ohio, for calculating areas of farming lands and for testing the accuracy of surveys made with the surveyor's compass.

DESCRIPTIONS FOR CONVEYANCES.

For definite and accurate descriptions of land in conveyances, it does not seem possible to devise a more precise and certain method than that of co-ordinates from geodetically determined reference points or origins. The present loose and indefinite descriptions in conveyances, upon which the tenure of a large part of the real estate of the country now depends, are disgracefully uncertain and frequently lead to excessive expenses of unnecessary litigation, and sometimes to costly errors of misplaced constructions.

CONVENIENCE IN CONSTRUCTING MAPS.

In the construction of maps and plans, co-ordinate determinations will be found especially convenient. After completing the survey of any portion of a district it is easy to place it in its proper position upon the map of the entire district with the certainty that other portions subsequently surveyed will fit into their proper places without the perplexity and the distortions frequently accompanying the attempts to unite two or more independent surveys made under the methods in common use.

SUMMARY OF ADVANTAGES.

A few of the advantages which may be expected to follow the general adoption of the co-ordinate method of surveying may be summed up as follows.

First—The attainment of the highest practicable degree of accuracy, as well in smaller local surveys as in more extended operations. The units of measurement which form the basis of the United States Coast Survey have been most carefully compared with those of the entire civilized world, and with the dimensions of the earth itself, and are verified to a degree of precision beyond which the present attainments of scientific skill have not passed.

Second.—Extreme simplicity of notation with ease and convenience of field work and computation.

Third.—Facility in graphic representation.

Fourth.—Absolute certainty of locations in descriptions for conveyances, and consequent removal of a fruitful cause of litigation and trouble.

ALTITUDES.

No change is proposed in the existing methods of determining the third ordinate or altitude. The most convenient mode of fixing this ordinate, pre-supposes that the form of the earth's surface, or of that surface which would be presented if the irregular surface of the land were razed to the level of the sea, has been accurately determined by geodetic operations, so that in ordinary surveying we have only to ascertain the heights of our points of survey above this imaginary level. This is done by using the spirit level, by measuring vertical angles and by barometrical observations. The first method admits the greatest degree of precision under ordinary circumstances, and is almost exclusively used for engineering purposes.

THE PUBLIC WORKS OF INDIA.*

(*Concluded from page 111.*)

Justice has been done to the work undertaken by the Civil Engineer in India by the Government Director of the Indian Railway companies. The Engineer had to contend against the forces of nature to a far greater extent than is the case in England. He had to overcome the difficulties which the gigantic features of the country placed in his way; he had often poor materials and inferior labor at his command; and he had to meet the dangers of exposure to a burning sun by day, and malarious vapors by night. To the aid of his skill and professional knowledge he accordingly had to bring more than ordinary courage and endurance. Many have broken down in the attempt, but their places have been immediately filled by others, and the result is exhibited in the thousands of miles of railway which thread their way over mountain passes, cut through thick jungles, and span huge and uncertain rivers.

From Bombay runs the line of the great Indian Peninsula Railway, proceeding in a north-easterly direction for thirty-three miles to Kalian, where it divides into two branches. Of these, one runs for 583 miles also in a north-easterly direction, to Jabulpur, the point of junction with the East Indian Railway, with a branch at the 276th mile to Nagpur, which is 520 miles from Bombay. The other takes a south-easterly course to Raichur, where, at the distance of 462 miles from Bombay, it has a junction with the Madras Railway. The total length of line is 1,287 miles.

The Jabulpur line of the East Indian Railway proceeds from its junction with the northeastern fork of the Great Indian Peninsular line to Allahabad, a distance of 229 miles, making a total distance of 845 miles from Bombay. Allahabad is on the main line of the East Indian Railway, which runs approximately parallel to the course of the Ganges valley in a south-easterly direction, curving from Delhi to Calcutta, or rather to Howrah, on the right bank of the Ganges, opposite to Calcutta. From Delhi to Allahabad is 390 miles, and it is 564 miles from Allahabad to Howrah. Besides the Jabulpur branch before mentioned, the East Indian Railway has a loop-line of 315 miles in length, between Kanu, 75 miles from Calcutta, and Lakhmisarai, which is at the 262d mile of the main line. From Delhi the line of communication is prolonged by the Sind, Punjab, & Delhi Railway, which runs first in a northerly and northwesterly direction to Lahore, a distance of 348 miles, and thence in a north-westerly course to Mooltan, 556 miles from Delhi. Of the projected prolongation of the Sind section of this line down the valley of the Indus to the port of Karachi, 109 miles from that place up the valley to Kotri are completed. The Oudh & Rohilcund Railway has a course of 414 miles of the main line running nearly parallel to that of the East Indian Railway, and 128 miles of branches. The Bombay, Baroda, and Central India Railway skirts the coast of the Arabian Sea and the Gulf of Cambay, and runs behind the isthmus separating that estuary from the Gulf of Cutch, to Wadhwan, a distance of 389 miles, with a branch of 31 miles to Dakoor and Pali. The Madras Railway runs from Raichur, the terminus of the southeastern fork of the Great Indian Peninsular Railway, in a prolongation of this line to Madras, which is distant 350 miles from Raichur, and 793 miles from Bombay. From Arconam, a point on this line 42 miles northwest of Madras, the southwest line of the Madras Railway runs for 201 miles to Erod, and then turning to the west to Beypur, on the western coast, 406 miles miles from Madras. Including four branches, the length of the Madras Railway will be 858 miles. From Erod the South Indian Railway runs for 168 miles to Nagapatam, on the Eastern coast, while by a second line running south it reaches Tuticorin. This main system of Indian railways, executed under the guarantee of the Government, is completed by the 156 miles of the Eastern Bengal Railway from Calcutta to Goalandu. The length, when complete, with the exception of the missing link from Kotri to Mooltan, will amount to 6,041 miles. Including the State lines, which are generally projected on a narrow gauge, the sanction of the Government has been given to the construction of 9,415 miles of railway. The total amount expended on Indian railways to 31st March, 1876, was £105,790,929 of which £93,720,794 consisted of guaranteed capital, and £12,070,135 of funds raised directly by the Government.

The whole extent of railway now completed in India is 6,497 miles, of which 261 miles were opened in 1875. Of the total length, 768 miles are constructed with a double, and 5,729 with a single line; 5,676 miles are on the 5 ft. 6 in. gauge, 27 on a gauge of 4 ft., and 794 on lines of a metre, or 3 ft. 3⅜ in. The division of gauge pretty nearly corresponds to the distinction between the guaranteed lines, 5,710 miles in length (which have been constructed by public companies, under a guarantee of 5 per cent. interest on the capital expended, given by the Government, and which have been laid on the 66 inch gauge), and the subsidiary lines which have been made by the State directly, on a smaller gauge. By dividing the capital of £93,720,794, defrayed from guaranteed share capital, debentures, or debenture stock issued by the companies, by the tabulated length of 5,710 miles open on these eight great lines, we arrive at the average cost of about £16,400 per mile over the entire net-work; while the cost of the 1,504 miles of the East Indian line alone is close upon £20,000 per mile which reduces that of the remaining guaranteed lines to an average of about £15,000 per mile. On the State lines the Government had expended, to 31st December, 1875, the sum of £12,070,135. Taking the lengths tabulated which amount to 751 miles, the cost of these lines, which are ten in number, appears to exceed that of the majority of the guaranteed lines, being almost exactly £16,000 per mile.

It only remains, in order to give a comprehensive view of the Indian railway system, to add that the total length of line sanctioned up to the present time is 9,416 miles. Of the 2,978 miles which remain to be finished, 502 miles are on the guaranteed lines of the South Indian and the Oudh and Rohilcund Railways, and the remainder are distributed over the State lines, seven of which are as yet without any part open. The total number of State lines, when this project is carried out, will be nineteen, and their aggregate length will be 3,216 miles. This includes the 508 miles of that very important link, the Indus Valley line, which, though made by the State, is properly designed on the usual Indian gauge of 66 inches.

In approaching the question of subsidiary communications, the question no longer lies between locomotive and horse propulsion; it rather arises between the respective advantages of land and water communication. That the utmost possible extent should be given to both modes of opening up the country there is no room to doubt. But two considerations are enough to show that the organization of water carriage ought to occupy the attention of a statesman. The first of these is that roads can be, and are, everywhere executed in detail, and aided by local exactions, and that such exactions may be multiplied to any extent without one road interfering with another. Combination is possible, but there is little room for any injurious competition. With water transport, on the other hand, the case is entirely different. The canals, or the artificial navigation of a great country, can only be properly executed as component parts of a well considered system. Another feature of canal communication, which in India assumes the utmost importance, is that the use of a canal as a highway is not the only, nor even in most cases the most important, service rendered to a district by its canals. They are, as we before said, the conduits of irrigation. It is true that the same quantity of water cannot be used at the same time to convey water borne traffic and to flood paddy-fields. But even the same bulk of water may be thus successfully employed. It may flow gently for hundreds of miles, bearing the traffic of the district on its surface, and then, instead of being allowed to waste its fertilizing store in the sea, it may be applied to the needs of the agriculturist. It follows that those who are so loudly calling for the canalization of different water-courses of India, are to a certain extent fully in the right. They but little, if at all, exaggerate the services which may thus be rendered to the agriculture of the country. How far they are correct as to the facilities that may be afforded for transport is rather a question of detail, dependent, to a great extent, on facts as to area, watershed, rainfall and other physical facts, which can neither be neglected nor taken for granted.

The importance of irrigation in India is not to be measured by money alone. To a certain extent, of course, a money valuation is not only possible, but must be the basis of every well-considered system of canal or of other hydraulic work. But we are little accustomed to realize in this country, the extent to which the inhabitant of India is dependent on the general rainfall. The meteorological phenomena of India are on a scale, and are ordinarily attended by a regularity, of which we can form no practical conception. Our stormy skies send us rain perhaps on 160 out of the 365 days of the year; but a difference of 30 days, either more or less, is one that hardly attracts any serious attention. But in India, when the monsoon rains fail, as they have recently again done, the result is famine. Famine at least can only be prevented by irrigation. In those districts where, as before mentioned irrigation is necessary, and where it may practically be ensured by hydraulic works, the execution of such works may be

* From the British Quarterly for April.

the means, in any case of drought, of saving lives, not by thousands, but by hundreds of thousands.

The ancient and simple method which has, time immemorial, been employed in India for raising water from wells for the purpose of irrigation, is the *picottah*. The work of a laborer engaged in this hydraulic operation bears a very strong resemblance to the game practised by English boys under the name of see-saw. A post, a portion of a tree, is driven into the ground adjacent to the well or other source of supply. Very often this takes root and throws out branches which afford a grateful shadow to the laborer. This post is forked at the top, and bears a long plank, which is notched near the middle, to prevent its slipping from the support, on which it can freely vibrate like the beam of a balance. A bamboo is attached to the end of the plank over the well, and a water-vessel is fixed to the bamboo. This forms the entire apparatus. The task of the laborer consists in walking backwards and forwards along the plank. When he approaches the loaded end the vessel dips into the water; when he returns to the other end, the vessel, full of water, is raised into the air to the height proper for discharge. The day's work finished, the native carries home his water-vessel, and also the bamboo, if the latter be of sufficient value to steal. The cost of raising water by this simple method is about the same as that by the more costly apparatus of a bullock wheel, that is to say, about £1 sterling for every 3,000 cubic yards of water.

This cost, low as it is when compared to the productive value of the water thus raised when applied to the land, is very high in proportion to the price at which water can be produced by well conducted public works. Sir Arthur Cotton, in a series of lectures on Irrigation Works in India, delivered at the School of Military Engineering at Chatham, in November, 1874, gives the following prices: For water raised fifteen feet by animal power, as in the case of the *picottah* or bullock wheel, 3,000 cubic yards per £1. For water raised twenty feet by steam power, 20,000 cubic yards per £1. For water stored in tanks constructed for the purpose, from 40,000 to 60,000 cubic yards per £1. For water drawn from rivers and distributed by irrigation canals, from 20,000 to 70,000 cubic yards per £1. If we take as a moderate average, for the sake of keeping to round numbers, the rate of 24,000 cubic yards per pound sterling, each entire yard of water will cost one-hundredth part of a penny. The average price of the water supply of London is 1*s.* 4*d.* per cubic yard, or 140 times as much.

In the impossibility which exists of giving within a limited space any estimation or exhaustive account of the main irrigation works completed, or in course of execution in India, it may be desirable to reproduce the principal features of the account given by Sir Arthur Cotton of the works on the Godaveri, which are among the most important in India. This river, as we have before remarked, has a course of 898 miles, and drains an area of 112,200 square miles. Its delta contains a million of acres. At the apex, or head, of this delta, the river is four miles wide, including two islands, which are covered with from three to ten feet of water in the freshes. When the river is full these islands divide its course into four channels, having an aggregate width of some 4,000 yards. At the close of the dry season the water is not more than one foot deep at the fords but in extreme floods it rises as much as thirty-one feet. The volume discharged in the former case is estimated at about 300,000 cubic yards per hour, which is less than a fifth part of the volume of the Nile at Cairo, when at its lowest in the month of June. But the discharge of the Godaveri in a thirty-one feet flood is given by Sir Arthur Cotton at 180,000,000 cubic yards per hour, while the October flow of the Nile, at its average flood for that, its highest month, has been accurately measured by Mr. Fowler at a little under 26,000,000 cubic yards per hour. The average height of the rise of the Nile, corresponding to this delivery, is 22½ feet. The floods of the Godaveri are comparatively brief in their duration, but the above comparison affords some measure of the enormous volume of water that at certain seasons comes down the river, a volume which of course complicates the work of the engineer to an extent of which those unacquainted with the localities can form but little conception.

The fall of the Godaveri from the head of the delta is at the rate of 1¼ feet per mile. The level of the adjoining land is twenty-eight feet above low water line, or about three feet under flood line. The land slopes rapidly from the edge of the river, so that the natural surface may be reached by a canal within 5 or 6 miles, if a water level be maintained intermediate between the old low water line and the flood line. This has been effected by the construction across the Godaveri of a weir, or, as it is called in Hindostan, an *annicut*, of masonry. This noble work is two and a half miles long and forty-eight feet wide, of which eighteen feet are level, and the remaining thirty feet form a curved slope. The level sill or platform of the *annicut* is fifteen and a half feet above the old low water level, and provision is made for raising this height an additional two and a half feet, in the dry season, by planks. The material of this immense river wall is hard sand stone, the surface over which the water flows being covered with well fitted and dressed blocks of two feet in thickness. Below the thirty feet of slope is a loose stone apron of twenty-five yards broad, composed of large blocks carefully packed, with a very slight slope.

From the middle and from the end of the *annicut* are led three canals, each of them sixty yards wide, and carrying eight feet of waterwhen full. The water is admitted to each by a head sluice, and this is accompanied by a lock a hundred and fifty feet long and fifteen wide, in order to accommodate the navigation of the canals and river. The fall of each canal is equal to the ordinary allowance, in the English fen districts, of four inches per mile, giving a current of two thousand five hundreu yards per hour, and thus conveying in all one million cubic yards of water per hour. Adjoining each head sluice, at a level four feet below that of the bottom of the canal, is constructed an under sluice. Each of these is capable of discharging a million cubic yards of water per hour. The object of these is, by opening at proper seasons, to scour out the bed of the river near the heads of the canals, and thus prevent the silting up of the latter, a precaution rendered necessary by the immense mass of *debris* annually brought down by the flood of the Godaveri. Iron posts, furnished with grooves, are built into the crest of the *annicut* in order to receive the planks above referred to as added in the dry season. These standards are eight feet apart and two feet six inches high. The planks are removed before the monsoon. It has occurred that freshes have come down the river while the planks were in place. No danger has hitherto occurred from this, but care is now taken to prevent it, as tidings of the rise of the river are obtained many days before the flood reaches the *annicut*.

This important work contains 800,000 tons of stone, besides many millions of bricks. It was constructed of sandstone quarried from a hill on the spot, and subsequently covered with two feet of harder stone, brought to the works from a distance by the navigation, when rendered available. An admirable hydraulic lime was burned from a limestone quarried within a few miles of the *annicut*.

The work has now stood for twenty-eight years, having only once been breached by a flood. This damage happily occurred at a time of year when no very considerable damage was caused to the crops, and the cost of repairs was not over the modest sum of £6,000. The water is carried in the canals at a level two or three feet above that of the adjacent land, to which it is admitted by sluices in the canal banks. Drains are cut between every two irrigating canals, to carry off the local rainfall, which is exceedingly heavy. Some of these drains are as much as 20 or 30 yards broad. As yet the system has been applied to the surface of only 600,000 acres out of 1,000,000 acres of the delta. It has already cost £600,000, and Sir Arthur estimates that the ultimate cost of the completed works, applied to the whole delta, will be about a million sterling, that is to say, a pound per acre.

The works in existence, in course of execution, or in a state of prospect, with reference to irrigation in India, are primarily divided according to the position of the great river basins in which they lie. They are tabulated as those of the Indus basin, the Ganges basin, the Mahanadi basin, the Narbada and Tafti basins, the Madras system of irrigation, and the embankments against floods in Bengal and British Burmah. We have before remarked that many of the canals are adapted both for irrigation and navigation.

As soon as the Sirhind Canal works are completed, there will be navigable communication from Calcutta up the Ganges, by the canal to the Sutlej, and down the Indus to Karachi. The delta canals of Madras are much used for boat traffic, as well as the high level and Cochrane's Canal.

It is impossible to condense in a simple paper, any adequate account of what has been done, what is now in course of execution, and what remains to do, in order to endow British India with an adequate system of primary lines of communication by land and by water, comprising under the latter head the services of irrigation as well as those of navigation. To tell, with some degree of precision and of detail, the story of one great work, is to indicate what we may repeat again and again over no inconsiderable portion of the 943,400 square miles which form the area of British India.

CORRESPONDENCE.

DALLAS, TEXAS, *May 1 t, 1877.*

EDITOR ENGINEERING NEWS:

SIR—I would like to know if you or any of your readers and correspondents have any experience with brick street-gutters. We have no suitable stone, are tired of plank, and seek a substitute not too expensive. Can you send me a cross section of a brick-gutter, and specifications for laying them down. Our grades are only 6 in. in 100 ft., and water is quite slow in the gutter.

Yours truly,

WM. JOHNSON, *City Eng.*

FOUNTAIN CITY, *April 23d, 1877*

EDITOR ENGINEERING NEWS:

SIR—I was lately called upon to establish the ¼ section corner with line between Section 2 and 3, T. 21, N. R. 11 W.: The corner was completely lost, and it was necessary to run out the whole line to establish the same. I found it by actual measurement, 83.03 chains instead of 85.61, government distance given; I established the ¼ corner at 44.23 chains from the north and at 38.80 chains from the south section corners. Section 2 was formerly sub-divided by a surveyor who seems to have divided it according to the number of acres, or giving full measure for fraction, and his corner consequently was several rods further south. Yours truly,

J. B.

ANS.—You have divided the line correctly to obtain the quarter corner. Areas do not enter into the location of corners; they serve as a check and are useful as pointing out the intention of the government.—[ED.

GALESBURG, ILL., *May 3, 1877.*

EDITOR ENGINEERING NEWS.

SIR.—I send you the following statement of facts in regard to a survey, and desire your opinion or the opinion of some of your subscribers who understand such matters.

On the line between sections 24 and 25 the middle corner is lost; there are no traces left of the witness trees. Field notes describe the corner as 40 chains 70 links from the west corner, and 39 chains 30 links from the east corner. The corner has been twice re-established by County Surveyors. One insisted on following the field notes, found the centre of the line and placed the stake 70 links east. The other insisted on placing the stake at the centre of the line, that the duty of the government surveyor was to divide the section equally, and that the memoranda on the field notes cannot be right.

Please reply and oblige one who has read ENGINEERING NEWS from its beginning and is much interested in it.

Yours,

G. C.

ANS.—In the absence of reliable evidence as to the original location of the corner in question the *only* way to proceed is according to the following proportion:—As 80 chains is to the actual length, by your chaining of the north line of the section, so is 39.30 chains to the distance from the east corner to the correct point of location of the quarter corner; in short, divide the line *pro rata*.—[ED.

IT is often the case that sewers become choked up because they are too large, there not being sufficient depth in the constant flow of water to carry off the ordinary obstructions, there, is a gradual deposit which in times fill the sewer.

These difficulties are obviated in the use of the *Salt Glazed Vitrified Sewer Pipe*. This pipe is made from a clay that, by the chemical action of salt, used while burning, becomes covered by a glazing that will not wear off, and is impervious to the action of acids, gases, steam, or any other known substances, and the pipe itself becomes vitrified. The surface being smooth as glass affords no lodgment for any of the substances passing through the sewer.

A series of tests made in Boston, Washington, and Chicago, which consisted in the "crushing test," "breaking test," and the "abrasion test," to which the different kinds of American and Scotch pipes were subjected, resulted in the favor of the *Akron Standard Salt Glazed Sewer Pipe* in each and every particular. This pipe is manufactured at Akron, O., the interest being one of considerable extent, the Akron Sewer Pipe Association, which combines three of the most extensive sewer pipe manufactories in America, viz: the "Akron Sewer Pipe Company," "Buckeye Sewer Pipe Company," and "Camp, Cook & Co.," having a combined capacity of from 1,200 to 1,500 car loads yearly.

The clay used is obtained from the banks adjoining the works, and is known as the 'Akron," or "Summit Clays," which analysis proves to be unequalled. By skilled labor and powerful machinery of the latest and best designs the material is rendered uniform. Under great pressure the pipe is made very compact, and at a high temperature becomes a thoroughly vitrified and iron-like body, imperishable and indestructible by any of the elements to which they may be subjected. The pipe is made in sizes from two inches to two feet in diameter, and of all forms, from the straight to the curved, embracing "Traps," "Elbows," "Slants," "Branches," etc.

The principle market for the past two years, has been in the New England States, where the Scotch pipe has heretofore monopolized the trade, although immense quantities of goods are shipped West and North.—*Merchant's and Manufacturer's Review.*

ARCHES;

CONSIDERED GRAPHICALLY.

(*Continued from page 116.*)

59. A shear at a joint, if desired, can be found by taking the mean of the two adjacent shears just obtained. A table which accompanies this section has been computed for the middle points of twenty divisions; it is intended to supplement the previous table of bending moments, and will serve as a guide for the calculation of any table with a greater or less number of spaces. Besides, it is easy to select from this table that combination of loads which will give on any parabolic arch, hinged at the ends only,

the maximum shear of either kind in any one division, one arrangement being the complement of the other. These shears, as should be the case, foot up very nearly to zero for an equal load on every joint. It is only necessary to calculate one half of the table, the other half containing the same numbers in the reverse order, and with the opposite signs.

It may be seen, from a comparison of this table with the one for M, that, as in a beam, the points of maximum flexure occur where the shear changes sign.

60. In the case of single span trusses, the maxima bending moments, and consequently the maxima stresses in the chords, occur when the bridge is entirely covered with the live load, and the greatest shear at any section, or the greatest stress in any brace exists when the bridge is covered with live load over one or the other, usually the longer, of the two segments into which the section divides the span. A simple inspection of the tables for M and F, lately given, will show that such rules are not true for an arch. Why this is so will be seen, if we consider the fact that the portion of arch, in Fig. 10, between B and the point where C A crosses the rib is under a bending moment of the positive kind, while from that point to A bending moments of the negative kind exist, and that an addition of another load near I, will increase most of the positive and negative moments in amount, while one placed on the left half of the arch will have an opposite effect. The shearing forces for the braces, depending on the stresses on the flanges, will be also affected in the same way.

61. An attempt has been made to represent, by the horizontal lines in the accompanying diagram, Fig. 13, those positions of the live load, or the extent of the loaded portion, which will give the maxima moments of both kinds at each of the nineteen points, and also that arrangement of the live load which gives the maximum shear of either kind at the middle of each division. The full line denotes the loaded portion of the span when the maximum positive moment occurs at that point whose number is placed at the end of the line, positive being understood to mean that kind of moment which would make a previously straight beam concave on the upper side; and the remaining portion of the span must alone be covered with the live load to produce the maximum negative moment at the same point. Thus the maximum positive bending moment at 2, and at 3 also, is found when the load is on allpoints from the left to 7 inclusive. A load from 8 to the right abutment gives the maximum—M. The maximum + M at 11 occurs when the arch is loaded from 9 to 14 inclusive. The extent of live load required to produce the greatest upward, or positive shear on the left of a vertical section through the web or brace in any division is indicated by the broken line drawn in its proper space, and a load over the complementary blank portion will give the maximum shear of the opposite kind in the same division. Thus, the maximum + F, at the middle of 3-4, is found when the load extends from 4 to 9 inclusive, and the maximum—F, at the same place, when the load reaches from 1 to 3 and 10 to 19 inclusive.

62. As a partial load, not extending to either abutment, will give the greatest M at some points, and as the same thing is true of the values of F, those writers who determine the greatest stresses by the usual test for maximum applied to an algebraic equation, which contains the expression for load as continuous from one abutment, must err in their results. We have endeavored to explain the construction of these tables carefully, so that, if a different number of points of division, possibly not equidistant horizontally, are desired for a specific design, the reader can reproduce them for himself, either by new computations or by interpolation.

63. It must be remembered that the steady or fixed load, unless distributed uniformly horizontally, gives some definite bending moment and shear, of one sign or the other, at each point, and these amounts must first be obtained from the tables or by diagram. Then when the rolling load is introduced, it may only be able, at some places, to reduce the amount previously existing, without making it pass zero and change sign. For instance, if, at a given point, the bending moment from fixed weight is +, the arrangement of rolling load which gives the maximum + M at that point will conspire with the steady load and give an actual maximum + M; while that arrangement of rolling load which, in itself, gives a maximum − M will reduce the moment from steady load. If large enough to prevail against the + M, the rolling load will produce an actual maximum − M; but, if not, it will only cause a minimum + M. Similar remarks might be made concerning shear. Finally, in every case, the direct thrust must be combined with the stress from bending moment, to give the resultant stresses in the rib.

As to an absolute maximum M of either kind, for a uniform load, it will be found, if we sum up the quantities in the table, to occur at thr 5th and 15th points of division, or at the middle of the half span. The loads to produce these values are seen in Fig. 13. The absolute ± F is found at the abutments, while another value, nearly equal in amount, occurs at the crown. These absolute maxima are found by comparing footings of the several columns.

As every additional weight increases H and therefore increases the direct thrust on a cross-section in the same proportion, while added weights on some points will diminish the previously existing bending moments and also the tension and compression which is caused by them, it is quite possible that the maximum resultant compression and tension in any portion of the flanges will be found for some other arrangements of loads than those which give maxima bending moments only. As the stress from bending moment depends on the depth of the rib and not on the rise of the arch,

(*To be continued.*)

NOTE.—Figure 13—which should have been presented at section 52, is unavoidably omitted in this issue.

In section 56 of our last, immediately before the italic sentence on the fourth line from the end of the paragraph, the words "in one figure representing positive or upward shear" must be inserted.

THE NEW YORK POST-OFFICE ACCIDENT.

The cause of the fall of a portion of the roof of the New York Post-Office building has been investigated by a coroner's jury, and also by a commission appointed by Postmaster James, acting under orders from Washington. We referred to the accident in our last issue, and gave some few particulars of the case at that time. The findings of the jury and the commission we give below and they are sufficiently explicit to call for scarcely any additional words of our own. That we have such definate results from the investigation is due largely to the fact that both bodies contained men well qualified to decide upon the matter, as will be seen when we state that, upon the coroner's jury were Mr. Richard M. Hunt, architect of the *Tribune* building, Mr. Leopold Eidlitz, at present in charge of the works on the Albany Capitol and the New York City Courthouse, Mr. Henry Fernbach, who has designed a number of large insurance company buildings, Mr. Richard M. Upjohn, who has now under his charge the Connecticut State Capitol at Hartford, besides several practical builders. Postmaster James called to his aid Theodore Weston, architect of the Equitable Building, Wm. D. Jardine, architect of the Western Union Building, Walter W. Adams, Superintendent of Buildings, A. J. Campbell, of the Architectural Iron Works, and three builders. The United States Grand Jury have also investigated the cause of the disaster.

It appears that the truss was of some thirty-five feet span, to carry a portion of a fire-proof roof, in place of a 12 inch wall which was removed. This wall itself rested on I beams and had caused such deflection and cracking of the ceiling beneath it as to call for remedy. The truss rested at one end upon a cross-wall and at the other upon the plate and purlin of a Mansard roof. The weight of the roof was even greater than we stated last week, the concrete filling over the corrugated iron arches being five inches thick at the crown of the arches and fourteen inches thick at its deepest part over the nine-inch rolled beams which carried the arches.

By the testimony of Mr. Thos. H. Oakshott, who was Supervising Inspector of Material, and in charge of the construction of the new Post-Office, it also appears that he was a stone cutter by trade and had been inspector of masonry; that he furnished Henvelman, Haven & Co., of New York with a lithograph of the other similar trusses, and directed Mr. Haven to take his measurements from a truss in position under another portion of the roof; and that Mr. Haven's offer was for $233, or $205 less than the cost of the original trusses, which were built by the Kellogg Bridge Company.

Ex-supervising Architect Mullett was questioned as to his professional training, and said he had opened his career as a civil engineer in Cincinnati, where he had afterwards picked up the ability to draw designs. When asked what he meant by the parallelogram of forces, and also the resultant of two forces, he declined to answer general questions touching his professional knowledge as an engineer. The engineer, Gen. Wm. G. Steinmetz, who was also examined, satisfied the jury of his good capacity and experience, but unfortunately he, the only one who possessed sufficient technical knowledge, had only advisory functions, and was not consulted, and knew nothing about the truss.

There is apparent the grossest carelessness and ignorance in regard to the resistance of materials and their proper disposition, and the public will naturally and rightfully ask how do we know that other of our government buildings have not been botched in the same way, and may not contain dangerous points of construction. In regard to the I beams spoken of below, with a deflection of 5½ inches, the strain on the square inch at the worst places must be not less than from 30,000 lbs. to 40,000 lbs.

Mr. Hill, the Supervising architect of the Treasury Department lays the accident to the faulty construction of the building in the first place as the prime cause of the disaster, Mr. Mullett says that Mr. Hill procured the removal of Engineer and Asst. Supt. Steinmetz, who had previously been in charge of the work, and this he considers as the real cause of the accident.

The verdict of the coroner's jury was as follows:

We find the immediate cause of the falling of a portion of the roof of the New York Post-Office, on the 1st. day of May, 1877, to be from improper and insufficient construction; but that the primary cause of the disaster is attributable to the incompetency of the agents of the Treasury Department charged with the erection and completion of this building, and that the United States Government is responsible for this calamity.

We further find that an excessive quantity of concrete was used in the covering of the roof, and that the load thereby imposed upon the iron roof-beams and their support exceeds the weight for which the iron construction was originally designed by more than 300 per cent.; that all of this is owing to incompetency on the part of A. B. Mullett, Supervising Architect in charge at the time the roof was designed, and his local employees, and that the civil engineer—the only party appearing before us competent to design and compute methods of construction—has, according to the testimony no authority in carrying out the construction. His functions are entirely advisory; and that the Supervising Architect and his employees, not themselves technically intelligent, omitted to recur to his advice when changes were made by their authority. It appears that, on the removal of a wall on the fourth story, the remainder of the wall on the fifth story, left standing by order of A. B. Mullet, supported according to his direction, was supported by two light fifteen-inch iron beams, competent to carry only one-fourth of the weight imposed upon them; that this wall was recently taken out, to be replaced by an iron truss, and that the cost of the truss was reported to the Superintending Architect at Washington, D. C., by the local superintendent here, and the expenditure approved by him, but no special drawing was made for the new truss and its outer support; that the understanding between the local superintendent and the iron-workers was for a truss similar to another truss then in the building. It appears that neither the local superintendent nor said iron firm had the necessary technical information to correctly understand the functions of the truss needed, or how such a truss should be constructed, and that, in consequence, the truss and its support gave way as soon as the temporary props supporting the roof-beams were removed.

Furthermore, we are of the opinion that the method now in vogue in the Treasury Department, in Washington, of designing and constructing government buildings throughout the United States, demands intelligence in local superintendents in this or similar emergencies, which the government has certainly not in this case been successful in securing.

The conclusions of Postmaster James' commission are:

1. That the girder introduced under the wall when the alteration was made in the United States Court room was so insufficient for the purpose that it must have long ago failed had it not been for the fortunate fact that the brick wall which it supported was a particularly sound and strong one, and that it proved to be not only practically self-sustaining, but also (on the principle that it contained a natural arch) to have been able to hold the weight of the roof besides, and that the said girder is so insufficient in proportion that, when now relieved, as it was by the wall, from all the weight of the roof and all the weight of that portion of the wall itself above its natural line of fracture, which runs at an angle from the extreme ends of the girder, nothing but the fact that it happened to be constructed of exceptionally good iron and the floor above it had never been loaded by an ordinarily great weight, has prevented the Criminal Court room beneath from having been the possible scene of a far more serious accident than that which has now occurred in the room above it. The girder has now a deflection of 5½ inches, with a length of 35 feet 2½ inches between its bearings. The extent of the crack in the ceiling of the Criminal Court room did not necessarily indicate the exact curvature of and consequent danger from the girder, for the ceiling has some self-sustaining power independent of the floor on which it is hung, as is proved by the fact that many of its suspending-rods are loose (the floor has sagged in places more than the ceiling). As the strength of the girder is impaired, although the main load it was intended to carry is removed, and as under no condition is it strong enough to support with safety that portion of the floor alone, which it is still called upon to carry, your commission, under the circumstances, may be excused if they recommend that it be either materially strengthened or that its place be supported by a new and properly proportioned girder.

2. The wisdom of the order to remove the wall and supply its place with a truss is evident.

3. The roof truss adjacent to the truss that failed, which carries substantially the same load, is proved to be sufficient to support the roof with safety.

4. The letters of April 2 and 3, from Mr. Oakshott, Superintendent, to Mr Hill, Supervising Architect, and of Mr. Hill to Mr. Oakshott, prove that a contract was authorized for a truss which would have been adequate to safely support the roof.

5. The fact that important elements of stability and strength in the model truss are not found in the new truss explains its failure. The omission of a rafter with its bracing, which was a main reliance for the safe support of the end of the horizontal portion of the truss above it, was the primary cause of the accident. Its omission left the whole weight of one-half of 575¾ square feet of roof, with its iron beams, corrugated iron arches, and unnecessarily heavy concrete; also of the matal roofing and accidental load to be borne by a single strut 19¼ feet long, formed of the 10-inch channel bars, having 2¼ inch flanges, and their sectional area 3 2-10 inches placed back to back 3¼ inches apart, in the first 14 feet 8 inches of which, from the base, there are but two separations through each of which passes a ¾-inch bolt. The strut stood absolutely free and without lateral bracings. It was manifestly utterly incapable of sustaining the load placed upon it, and, as might of been expected, crippled (bent sideways) at a point three feet below its union with the truss. As no provision was made to brace the top chord of the truss laterally, either by bolting the deck beams of the roof to it directly or with angle irons, or by notching them on to it, it was deficient in lateral stiffness, and in danger of failure, of crippling the upper chord.

Finally, the present accident is due to two causes:

1. That the truss erected did not correspond with that recommended by Superintendent Oakshott, approved by Supervising Architect Hill, and apparently contracted for by Messrs. Henvelman, Haven & Co.

2. That the shores were removed and the truss was subjected to its load before it was examined by a person competent to determine if it was constructed in conformity with the contract.

Your commission considers that it is perhaps a fortunate circumstance that this accident, sad as it is, has led to the detection of the radical weakness of the hidden girder of the ceiling of the United States Court room, the continuance of which is now a source of jeopardy, and the community has great reasons to be thankful that they have been spared the details of a calamity far more appalling in its character.

THE FALL OF THE WINNEBAGO COUNTY COURT-HOUSE.

But a little more than ten days from the occurrence of the New York Post-Office disaster, we are called upon to notice the downfall of the Winnebago County Court-house at Rockford, Illinois, which took place Gay 11. This building was designed by Henry L. May, of Chicago, under an advertisement for plans in 1875, and Mr. W. D. Richardson, of Springfield, Illinois, obtained the contract for its erection, by a bid of $165,000. The structure was to be of brick, faced with Illinois stone, surmounted by a wooden roof and a massive stone dome. The corner-stone was laid June 22, 1876, and the work has since progressed at a reasonable rate. The roof was not yet entirely in place, but the stone cornice was being put on. Two pavilions on each side of the front entrance rise about thirty feet above the level of the cornice, and a dome between the two was 119 feet from the ground. It was supported by the front walls on the north side, and by two iron columns, from ten to twelve inches thick, on the inner side. These columns rested upon a brick wall, about thirty feet high, extending from the ground floor to the floor of the court room. Upon the top of the columns was a wrought-iron girder which supported the brickwork and stone veneer of the dome. As stated in a dispatch, it appears that the walls were entirely inadequate to hold the immense weight of the iron pillars and the mass of masonry of the dome which rested upon the pillars. The lower brick walls were crushed by the weight and crumbled, bringing with them the entire interior of the building, taking all the rafters and the corrugated iron ceiling of every room, with its concrete filling. Nine men have died from injuries received at present writing, and others are maimed for life. The outer walls remained standing, and some few of the men saved themselves by quickly taking refuge on them and in the window openings; among this number were W. D. Richardson, the contractor, and F. E. Latham, the Superintendent, who were on the upper part of the dome, and who are said to have been *talking of the probability of its falling*.

To whom blame should be imputed for this catastrophe it is impossible to say until we are put in possession of the expert testimony in the matter. The contractor has already ascribed the cause of the disaster to the architect, as he claims that the plans were strictly followed and the wall overloaded. It is stated that he has substituted stronger construction in some cases at his own expense, and that he has appealed for permission to strengthen supports, but was refused. If it is true that he entertained serious doubts of the building's strength, he ought to have refused to go on, and, so far, would be morally liable. It is worthy of note that he is said to have been discussing probabilities at the time of the accident. There seems to be a great faultiness in the construction of public buildings, and it is high time that decided action should be taken to prevent such calamitous occurrences. If the designer or constructor of a building, or any kind of a structure,

which, by falling through his fault, occasions the loss of life, should suffer the penalty for manslaughter, the effect of such severity would be wholesome. The Detroit *Free Press* remarks, "Designs for public buildings in which safety or solidity are sacrificed in the slightest degree to beauty or artistic proportion should be ruthlessly condemned; and if all these qualifications cannot be combined — and there is no reason to believe that that they cannot be with competent architects or builders — the former are infinitely to be preferred to the latter."

As to government buildings, the sources of trouble are well set forth in the reports in another column. In regard to other public buildings the difficulty is of another nature, depending upon the manner in which designs are obtained and contracts entered into. Unfortunately there are men, reputed to belong to our profession as well as to the allied profession of architects, who are really incompetent to plan and to carry out works which they aspire to design. Some way is needed of weeding out such hangers-on, and of making them powerless to waste money and jeopardize lives. A board of supervisors advertise for plans of a public building. It is seldom that they are competent to judge of the strength of the proposed construction and they rarely call expert judges to their aid: generally the design which gives the most ornate building at the least cost wins in the competition, practically introducing the requirement of sacrificing strength to looks, unless some private schemes have to be furthered at the same time. Then the contract is let to the lowest bidder, or, as it generally reads, to the lowest responsible bidder, although the case is rare where contractors' bonds have been enforced in case of failure. As a contractor's pecuniary interests are likely to be opposed to those of the other party, a superintendent must necessarily be employed to see that the specifications are carried out. If the superintendent is competent, well and good; but no enforcement of a contract for a poor and weak design will ever bring forth a good structure.

When we think of a bridge as opposed to a public building, there occurs to us one reason why a bridge that is somewhat deficient in stength may not show its weak points by failure, while the building excites suspicion; and this arises from the fact that the moving load forms so large a portion of the gross load in the former, and so little in the latter case. That some highway bridges still stand may be ascribed to the fact that they never have felt their greatest possible load.

To ensure a good design it is necessary that the submitted plans should be carefully examined and approved by men capable of judging, men selected for the task, and not office-holders by political nomination and election; that the contract should be let to a reputable builder at a reasonable and living price; and that the work in progress should be thoroughly supervised by one who has the ability and the power to modify minor details, if necessary. To put on a poor builder, and then to expect the superintendent to obtain good work from him, seems a strange requirement, but we have known those in authority who would do exactly that thing.

If we would single out the leading features which characterized the late Convention of Civil Engineers in New Orleans, it would be the princely generosity of the various railway companies which provided free transportation for so great a distance for so many people, the magnificent hospitality with which the members of the American Society and their guests were entertained by Capt. Eads, through his assistant, Mr. Corthell, and the sociability and good feeling that prevailed throughout the entire proceedings both in the meetings of the Society and in the excursions following.

The Eastern members received free transportation from New York city to Louisville by the direct routes thereto; at Louisville the following circular letter was furnished to all properly accredited members and guests:

Louisville & Great Southern Railroad Line.
Mobile & Montgomery Railroad,
New Orleans & Mobile Railroad,
New Orleans, St. Louis & Chicago Railroad Line.

LOUISVILLE, *April 20, 1877.*

Dear Sir: The courtesies of the lines between Louisville and New Orleans are hereby tendered to yourself and lady in passing to and from the ninth Annual Convention of the American Society of Civil Engineers, to be held in New Orleans, the 24th, 25th, and 26th days of the current month.

The presentation to conductors of this invitation, bearing the official stamp of Transportation Department, will secure you free transportation until May 15th, proximo.

E. D. STANDIFORD, *President.*
H. VICTOR NEWCOMB, *Vice Pres't.*
D. W. C. ROWLAND,
Gen'l Sup't Transportation.
F. DE FUNIAK,
Chf. Eng. & Sup't Machinery,
Louisville & Great Southern R. R. Line.
D. B. ROBINSON, *Supt New Orleans & Mobile R. R.*
E. D. FROST, *Gen'l Manager New Orleans, St. Louis & Chicago R. R. Line.*

To appreciate the extent of this munificent courtesy of the foregoing railroad officials, we may mention that the excursion train was made up of two regular coaches, two Pullman sleepers, and the Directors' car of the Louisville & Great Southern R. R. Line. The train was under the care of special conductors, the right of way was granted it throughout, and it waited at New Orleans an entire week to convey the party back to Louisville. The route in going was *via* Nashville and Mobile; in returning it was *via* Jackson, Miss., to Grand Junction, and thence over the line from Memphis to Louisville. The Western members and guests were furnished free transportation from Chicago to New Orleans and return, by the kindness of the Illinois Central R. R. Co. and the New Orleans, St. Louis & Chicago R.R., Co., a total distance of 1,860 miles, and in whichever direction it was decided by any of the party that they would return home, free transportation was immediately procured.

In New Orleans every facility for seeing the city was provided by the local committee, and they, with many of the residents, were indefatigable in contributing to the enjoyment of the occasion. Capt. Eads' generosity in providing steamers, and such a capable director of ceremonies as Mr. Corthell, has already been referred to, while to the U. S. officers on duty in New Orleans the visitors are very much indebted for the considerable share which they took in entertaining them wherever and whenever they had the opportunity.

Heretofore the Conventions have been held in cities to which the members came by various and widely different routes of railway; hotel accommodations were at the selection of each individual; the Convention was occupied largely with the reading and discussion of papers, the excursions were necessarily somewhat divided, and after they were over the members hurried away as they came, by different routes, knowing but little more of each other than before they met. In this last Convention there were many innovations on this method, and, as we believe, to the profit of all alike. The number in attendance was, we are told, the largest of any Convention yet held by the Society; there was a unanimous sentiment prevailing in favor of an early adjournment of the Convention, and the improvement of all the time possible in becoming better acquainted with each other, and so interchanging opinions more freely than could, or would, be done in formal discussions; the peculiar nature of the excursions, consisting of long intervals of time passed on board the cars and steamboats contributed to the more intimate acquaintance with each other, while the latest innovation of admitting ladies to the Convention dinner and to a prominent share in the pleasure excursions following, all contributed to render this meeting of Engineers an occasion of peculiar enjoyment and relaxation from the usually very practical and severe duties in which they are generally engaged.

Where the next Convention will be held will not be known for some months to come; we hope to see by the time that it does meet, a large increase in membership and influence of all the societies, and a very general desire of the profession to be present at this Annual meeting of the representative Society of the Country, and by so doing give their influence towards the exaltation of Civil Engineering to its proper place as the leading profession of civilization.

We are pleased to notice that the Franklin Institute have honored Mr. P. H. Dudley's Dynagraph with a gold medal.

The city of Detroit has failed to secure legislative sanction to the scheme of offering $500,000 bonus to a tunnel company. Those in favor of a tunnel are now endeavoring to secure private subscriptions and co-operation.

Personal.—John Ryall, C. E., has been re-elected City Engineer of Fort Wayne, Ind.

The Lehigh R. R. company are said to meditate following the line of action of the Reading company towards those locomotive engineers who belong to the Brotherhood, that is, creating an insurance fund for heir benefit, and then giving them notice to withdraw from the Brotherhood or leave the R. R. company's employment.

At 3 o'clock Thursday, Gen. Sooy Smith, P. B. Wight, and Edward Burling, presented their report on the Rockford calamity, at which time after being read, the jury decided to fully examine each of the above named gentlemen individually, not in the presence of each other. The report of the Committee is written, and is an elaborate document. It took over an hour to read it, and it went into every detail of the building, and is in itself a most complete description of the causes of the accident. This report, while pronouncing the plans of Gay radically defective, at the same time fully realizing the extreme delicacy of their position, show that Mr. Richardson, Mr. Latham and the county Board were also in a measure to blame.

We hope to be able to give the whole or part of this report next week.

CONVENTION OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS.

NEW ORLEANS, *Friday, April 27, 1877.*

At 10 A. M., the *LaBelle*, with 128 excursionists on board, backed out from the levee and steamed away towards the Gulf of Mexico. The weather was unexceptionable; the scenery was novel to most of the party; there were several points of historic interest to be passed; the invited guests from New Orleans were assiduous in pointing out the objects of interest along the river and in explaining the methods of draining and cultivating the plantations; the opportunity for more intimate acquaintance among themselves was quickly improved by all present, and the good feeling thus engendered at once banished all sense of monotony and gave to this crowning excursion of the Convention a constant charm from first to last which will long be remembered by all those who participated in it. The following is a list of the excursionists with their addresses so far as we were able to obtain them:

Frank C. Allen, 66 Vernon st., Boston; James Archibald, Ch. Eng. D. L. &. W. R. R., Scranton, Pa.; Frederick Brooks, Asst. Eng. Boston W. W.; John Bogart, Treasurer, and acting Secretary, of Convention American Society of Civil Engineers, and Mrs. Bogart, 36 Union square, New York; Mr. and Mrs. Balantyne, N. O.; Gen. G. T. Beauregard, Jas. Browning, Louisville; H. E. Stevens, C. E., St, Paul, Minn.; Louis G. F. Bouscaren, Asst. Eng. C. S. R'y, Cincinnati; William B. Cogswell, Mine La Motte, Mo.; Elmir L. Corthell, Asst. Eng. South Pass Jetty Works, Port Eads, La.; David W. Cunningham, Asst. Eng. Boston W. W., South Framingham, Mass.; Oliver E. Cushing, Agt. Lowell Gaslight Co., Lowell, Mass.; Frederick De Funiak, Chief Engineer and Supt. Road Department, L. & N. R. R. and Mrs. De Funiak, Louisville, Ky.; M. T. Endicott, C. E. U. S. Navy, New London, Chas. A. Ferry, Asst. Eng., 18 City Hall, New Haven, Conn.; Desmond Fitzgerald, Supt. Cotchituate W. W'ks, Boston, Mass.; John E. Earley, Res. Eng., C. S. Ry., Somerset, Ky.; Henry Earnshaw, 4th and Race sts., Cincinnati, O.; Clarence S. Ellis, City Hall, Boston; Charles E. Emery, 7 Warren Street, N. Y., Albert Fink, 226 Broadway, Louisville, Ky.; Henry Fink; J. Foster Flagg, City Eng. Meadville, Pa.; Caleb G. Forshey, U. S. Engs. office, 23 Rampart st., New Orleans, La.; Wilbur F. Foster, Burns' Block, Public Sq., Nashville, Tenn.; James B. Francis, Ch. Eng. Locks and Canals, Merrimack River, Lowell, Mass.; Sidney T. Fuller, Ch. Eng. P. W. & B. R. R., Phila.; John Griffen, (Clarke, Reeves & Co.,) Phœnixville, Pa.; A. B. Hill, Asst. City Eng., 18 City Hall, New Haven; Arthur Hobart, Aetna Woolen Mills, Boston; Clemens Herschel, 66 State st., Boston, Milton G. Howe, Ch. Eng. H. & T. C. R. R., Houston,

Texas; Charles W. Howell, Major of Engs. U. S. A., New Orleans; William E. Kelley, New Brunswick, N. J.; Eugene C. Lewis, Sycamore Mfg. Co., Nashville, Tenn.; Thomas D. Lovett, Cons'g and Prin. Eng. C. S. R'y, 70 West 3d st., Cincinnati; Charles MacRitchie, 105 Wisconsin st., Milwaukee, Wis.; Niles Meriwether, Chief Engineer, N. O. St. L. & C. R'y, McComb City, Miss.; P. N. Moore; Robt. Moore, 1221 St. Ange av., St. Louis, Mo. Edward S. Philbrick, Cons'g Eng., 12 West st., Boston; Franklin C. Prindle, Sec'y Am. Dredging Co., 10 South Delaware av., Philadelphia; Alfred L. Rives, Gen. Supt. M. & O. R. R., Mobile, Ala.; W. Milnor Roberts, Ch. Eng. N. P. R. R., 23 Fifth av., New York; William Rotch, Ch. Eng. Water Works, Falf River, Mass., Mrs. Rotch; Wm. H. Searles, Div. Eng. N. Y. State Canals, Rochester, N. Y.; Joseph S. Sewall, St. Paul, Minn.; Wm. Sooy Smith, Maywood, Ill.; Charles H. Strong, 101½ Water st., Cleveland, Ohio; Frederick W. Vaughan, V. Pres. Louisville Bridge & Iron Company; and Mrs. Vaughan, Louisville, Ky.; Charles D. Ward, 36 Hudson street, Jersey City, N. J.; Henry D. Whitcomb, Ch. Eng. James River Improvement, Richmond, Va.; Henry M. Wightman, As't City Eng., City Hall, Boston; William H. Wiley, (John Wiley & Sons) 15 Astor Place, New York; William E. Worthen, 63 Bleecker st., New York; Arthur S. C. Wurtele, 10, Jay at., Albany, N. Y.; Arthur Beardsley, Prof. Mechanics and Engineering, Swarthmore College, Swarthmore, Pa. Charles B. Brush, (Spielman & Brush) 40 Hudson st., Hoboken, N. J.; Emory C. Davis, Northampton, Mass.; Robert Fletcher, Prof. Civil Engineering, Thayer School, Dartmouth College, Hanover, N. H.; Charles M. Harris, 61 Broadway, New York; Horatio Seymour, Jr., Utica, N. Y.; Arthur Spielmann, (Spielmann & Brush), 40 Hudson st., Hoboken, N. J.; Lorenzo M. Johnson, Eng. K. & D. M. Ry., Keokuk, Iowa; Thomas J. Long, Asst. Eng. Dept. of Docks, 28 West 60th st., New York; Alfred Noble, 85 Washington av., Detroit, Mich.; Frank O. Whitney, Boston; Samuel Whinery, Div. Eng. C. S. Ry., Chattanooga, Tenn.; E. A. Doane, Meadville, Pa.; W. H. Newton, Chicago; Chas. R. Flint, New York; D. E. McComb, C. E.; Washington; Frederick W. Merz, Louisville, Ky.; Sanford Horton, New York; E. Powell, M. D., Chicago; J. H. Gardner, New Orleans, La.; B. M. Harrod, N O.; H. P. Davock, C. E., Detroit; R. L. Engle, Chattanooga; Prof. W. Watson, Boston; Arthur Macey, N. Y., city; Prof. L. E. Cooley, Evanston, Ill.; Major C. H. Boyd, U. S. Coast Survey.; J. A. Hayward, C.E. U.S.Eng., N.O.; A. S. Tyler, Lowell, Mass.; Benj. McLeren, St. L. & C. R. R., N. O.; C. M. Perin, Supt. N. O. & C. R. R., N. O.; L. S. Olmsted, Jacksonville; B. F. Morse, City Engineer, Cleveland, O.; Wm. A. Smith, *Railway Review*, Chicago; O. B. Green, Chicago; F. W. Clarke, C. E., Chicago; J. F. Goodhue, C. E., Chicago; A. B. Clifton, N. O.; T. S. Hardee, N. O.; Mr. and Mrs. Karner, N. O.; Miss Parker; Wm. Washburn, N. O.; Messrs. Morgan, Mathews, Owen, Tomlinson, Ward well, of New Orleans; Mrs. Underhill, Chicago; Bradish Johnson, N. O.; Richard Scriven, Civil Engineer; James Freret, Architect and Civil Engineer, N. O.; Col. A. F. Wrotnowski, N. O.; Frank H. Taylor, Special Artist of *Graphic*, Philadelphia; W. H. H. Judson, New Orleans *Times*; Mrs. Judson, and Miss Judson; Judge J. H. Kennard, N. O.; A. M. Granger N. O.; J. W. Putnam, New Orleans & Mobile R. R., Mrs. Putnam, Pascagoula; Miss Pitkin, Geo. H. Frost, ENGINEERING NEWS; Miss Hunt, Chicago.; Mrs. Mason and Miss Mason, of Ann Arbor, Mich; Owen Meriwether, Civil Engineer, Memphis; J. A. D'Hemecourt, City Surveyor, N. O.; Geo. A. D' Hemecourt, N. O.; Lieut. Chas. E. L. B. Davis, U. S. Engrs. N. O.; Leon Fremaux, Asst. City Engineer; W. A. Belknap, Louisville, Ky.

The most interesting historic ground passed during the forenoon was the scene of the battle of New Orleans. At 2 P. M., the *LaBelle* came to a landing at Magnolia Plantation on the west bank of the river, where the party were enthusiastically and cordially welcomed by its hospitable proprietor, Col. C. B. Lawrence, who had prepared a most generous lunch for their refreshment, and who placed all the resources of the plantation at their disposal for their entertainment. After the usual opening salutations of such an occasion, and the hearty enjoyment of the good cheer provided for them, the party were invited to ramble over the place at their pleasure; the ladies were taken in carriages through the orange grove, which is the largest but one on the river, and shown so much of plantation life as could be shown in a short time: the gentlemen explored the sugar house which was a most extensive affair and filled with ponderous machinery; they found the four great English steam plowing engines, and plows, of Fowler's manufacture, of considerable interest, and after these a hasty look at the plantation buildings, and the field hands at work in the cane-fields, after which all came together again in the host's hospitable dining hall where some very happy speeches were made by W. Milnor Roberts on behalf of the engineers, and in return by Col. Lawrence, General Beauregard, and Bradish Johnson, Esq. There were also a number of very charming ladies belonging to Col. Lawrence's household, who added very materially to the other attractions of the place, and whose acquaintance, we have no doubt some of the younger men of that boating party would like to renew during their summering at the north this season.

In consequence of the freshening of the weather, at nightfall the Captain of the *LaBelle* deemed it prudent to "tie up" till morning at the north end of the "Jump" a broad crevasse, and at which point the Mississippi widens to about 8,000 feet. The next morning some of the wakeful ones reported having seen a few mosquitoes flying about the cabin during the night, but it was generally ascribed to nervousness on their part, although it was unanimously voted that sleeping along side of a Louisiana swamp was not a pleasure to be courted very often. At day-break the boat was once more under way and shortly after breakfast the party landed at Eadsport, the new and rapidly growing seaport city of the Gulf. The most complete accounts of the work done at South Pass by Capt. Eads, at present in print, have been published in Vols. III and IV of ENGINEERING NEWS; for the best description of the inception of the work, the construction of the "mattresses" and the effects of the jetties in deepening the South Pass from 7 feet to very nearly 21 feet, in less than two years time, we must refer our readers to the very interesting article on pages 180 and 181; Vol. III, by D. W. Bowman, C. E. At page 244, Mr. J. A. Hayward, C. E., of New Orleans, has taken an opposite view of the subject from that of Mr. Bowman, and his article is illustrated by a plat of the passes; in the current volume the works at the head of the passes are illustrated, and a letter from E. L. Corthell, the energetic and efficient Assistant Engineer in charge, explains their uses, while the more recent article of Mr. Schmidt describes the method of obtaining the slope of the river by leveling. The jetties at South Pass are as yet an experiment, the success of which must be determined by time. A great deal has certainly already been accomplished by Capt. Eads and his boldness in undertaking so vast an enterprise under such difficulties, and his energy and courage in carrying it forward to its present results deserve the highest commendation and a generous pecuniary reward, and it cannot but be the sincere wish of every one who realizes the great advantages which must accrue to southern commerce by the permanent maintenance of a deep channel from the Gulf of Mexico to New Orleans and other river ports, that the enterprising contractor will make a complete and lasting success of the undertaking in which he is engaged. Col. W. Milnor Roberts and other eminent engineers who have visited the works at South Pass and who have made the subject of the hydraulics of great rivers the study of a lifetime, are positive in expressing their confidence in the efficiency of the present system of jetties; to time and the great river itself must be left the final solution of the problem.

The engineers' office at Eadsport was the rallying place of the party, and Mr. Schmidt, the very able assistant engineer in charge, soon found business enough in trying to answer a continuous stream of questions about current velocity, various depth contours, profiles, sections, mud-lumps, the scour of the river, to say nothing of a multitude of other subjects upon which he stood a most searching cross-examination by men who were familiar with the subject of hydraulics and who had come to South Pass to gain information. But Mr. Schmidt had learned the Mississippi pretty thoroughly and for every question had an answer, and a map to illustrate it.

The great river is an immense subject for study and the accounts of the phenomena already noted by its indefatigable human antagonists at South Pass would fill a volume; the working force is, however, so small that there is no time for anything but the regular daily work and therefore much that would be of general interest must remain with the engineers in charge until they find the time to give their brethren of the profession the benefit of their observations. We hope, however, we may from time to time be allowed to give to the readers of ENGINEERING NEWS an account of what is being done in the conflict between human skill and energy and the great river that drains a continent in its passage to the sea.

As an indication of the variety of observations that have to be made constantly and daily placed on paper for preservation and study, we note the following as the arrangement of drawings in the office:

Charts of Jetty Channel.

Profiles, plats, etc., referring to construction of Jetties.

Profiles and Cross-sections at the Jetties.

Profiles, Plats, etc., referring to Works at Grand Bayou.

Profiles, Plats, etc., referring to construction of Works at Head of Passes.

Profiles and Cross-sections at Head of Passes including sections in South Pass, Pass A l'Outre, and S. W. Pass.

Gauging Notes and Surface Slopes.

Under these headings were maps innumerable, in colors and in lines, and to be able to read them intelligently requires considerable study and practice. The working hours of the engineer corps are from 7½ A. M. till dark; it is work all the time, and every man must be in readiness to respond to calls upon him at any hour, day or night, or Sunday. A complete journal of every day's work is kept and it is usually the case with the engineer corps that after working on the river all day that they must continue their labors far into the night in recording their notes and studying the problems that are constantly arising for solution. A telegraph report of work is forwarded daily to Capt. Eads, who, wherever he is, is watching the great work he has undertaken.

All of the visiting party, who chose to go were taken on tugs to make a close inspection of the jetties. The excursion to South Pass was under the direct supervision of Mr. E. L. Corthell, from first to last, and certainly that gentlemen, Mr. Schmidt, his first assistant, and Mr. Karner, the cashier of the Jetty Company, left nothing undone to make the excursion alike pleasant and profitable to all.

After some hours thus agreeably spent at Eadsport the party were taken on board of the U. S. Revenue cutter, Jno. A. Dix, and the large steam tug, E. B. Ward, and after a trip on the Gulf and up South West Pass were re-embarked on board the *LaBelle* at the Head of Passes about 5 P. M., on Saturday. The time spent on the Gulf of Mexico was especially enjoyed, and notwithstanding the odious "ground swell" peculiar to those waters, when the two parties met on board the *LaBelle* to compare notes of experience, alligators, etc., everybody had proved to be regular "old salts" in resisting the peculiar influence of "ground swells," except—we are sorry to mention it—the amiable and genial chairman of the Convention, who lost his legs completely soon after turning the corner of the west Jetty, and did'nt regain them until we sighted the first alligator in the placid waters of the South West Pass. We noticed several others, however, looking long and steadily into the blue waters of the Gulf, but supposed they were watching for sharks and porpoises. After supper the company listened to short speeches from Col. W. Milnor Roberts, Gen. Beauregard, E. L. Corthell, and Judge Kennard, of New Orleans; votes of thanks were passed for the hospitalities which had been extended to the Convention, and after three cheers for the jetties, Capt. Eads and Mr. Corthell, and the singing of the "Star Spangled Banner" the company retired for the night, to a sleep undisturbed by the pestiferous mosquito, and from which they were aroused by the arrival of the boat at the New Orleans landing at 8 A. M. As engineers are all church-going people, so they all went to church in the forenoon, and remained quietly in the hotel parlors all the rest of the day, thus setting a good example for the wicked people of the Crescent city. The

influence of Moody and Sankey on the visitors from Boston was especially noticeable in this respect.

On Monday many of the visitors left for their homes; a considerable party visited the Bonnet Carre Crevasse; others visited objects of interest in the city; in the evening there was another trip on the river, in the "Protector" and a visit to the Monitor Canonicus lying in the river, where the party was most politely received by the officers in command and shown through every part of the vessel. The next morning about thirty of the party left for Galveston in company with Capt. Howell, U.S. Engineer, to inspect the government improvements at that place; others left by the regular Chicago train at 7½ A. M., and the eastern members and a part of the Chicago company left at 10 A. M. on the special train for Louisville, which returned to that city over the New Orleans & Chicago Railroad to Grand Junction, thence over the Louisville & Memphis road to Louisville, arriving in this latter city at 5 P. M. Wednesday. In passing over the New Orleans & Chicago road, the party dined at McComb City, where a most excellent repast had been provided for them by W. P. McKinley, Supt. Louisiana Division, who accompanied the party from New Orleans to Canton and devoted himself to providing for the comfort and entertainment of the party while in his division. The run from Grand Junction to Louisville was made in about 10 hours; the line traverses the finest region which we passed through during our absence, and under the superintendence of its very efficient corps of officers, the Louisville & Memphis R. R. is now one of the finest roads in the country, and the condition of its track and rolling stock is being steadily improved. The road crosses the Tennessee river by a magnificent iron bridge of eleven spans of 200 feet each and a draw, erected by the Louisville Bridge Company, who we soon learned, erected all the bridges on the line, and who are perhaps the leading bridge builders of the Southern States. A number of the party were allowed to get off the train at the west end of the bridge over the Tennessee, and with Albert Fink, the well-known Chief Engineer of the Bridge Company, and Mr. Vaughan the Vice-President, to answer any questions, proceeded to inspect the structure while walking over its entire length.

At Lebanon Junction the party found dinner awaiting them, and in this connection we think it is but just to state that at this eating station we found the most satisfactory entertainment with which we had met anywhere on the whole route over which we passed during the week, not excepting even the St. Charles Hotel of New Orleans.

At Cane City a detachment of the party left the train for a flying visit to the celebrated Mammoth Cave only nine miles distant; the balance of the party now considerably reduced in numbers kept on to Louisville, and thence homewards by the respective routes thither.

The Convention from first to last was an exceedingly enjoyable and profitable one, and we have no doubt will be remembered with pleasure by both the members of the Society and their guests, who were so fortunate as to be participants on the occasion.

THE PERMANENT SUPPLY WATER WORKS OF BALTIMORE.

One of the greatest engineering works now in progress is that to supply the city of Baltimore with water, and the gentlemen in charge of it have been so busy pushing it forward that they have had very little time to talk about it: in consequence of which not many people outside of the city know anything of it, and comparatively few have any idea of the immensity and difficulty of the works that are now so quietly progressing to supply them with an almost unlimited supply of the necessary article of water. One of our correspondents lately called on Mr. Robert K. Martin, the engineer in charge, who was so obliging as to show him over the line of works, and we are thus enabled to lay the following particulars before our readers.

Baltimore is at present supplied with works having a capacity of about 15,000,000 gallons a day, which comes from Jones' Falls to Lake Roland, whence it is brought by a conduit 3¾ miles long to Hamden reservoir and Druid Lake. From the latter, which is 53 acres in extent and 217 feet above tide, one portion of the water is raised by powerful steam pumps to a high service reservoir 350 feet above tide, for supplying the highest region of the city; a second part is supplied direct to the mains; and still another portion is allowed to pass to Mount Royal reservoir, which is only 150 feet above tide so as not to give too high a pressure to the lowest portion of the city.

The supply having been found to be insufficient in the summer season, it was resolved to increase it temporarily by erecting, near the Gunpowder River, a pair of Worthington's duplex compound pumping engines, capable of raising 10,000,000 gallons a day from that river, over a hill 265 feet high, to Roland Run, a tributary of Jones' Falls above mentioned. This arrangement, however, was not sufficient for some of the more enterprising of the Baltimoreans, and a new plan was devised; and it is now being carried out, notwithstanding considerable opposition by interested parties, by the capable and energetic civil engineer of the Water Commission, Mr. R. K. Martin, who had charge of the previous works, erected in 1858. The source of the new supply is the Gunpowder River, which at about nine miles from Baltimore makes its nearest approach to the city, as at this point it takes a bend in another direction. Advantage is taken of this turn to form a dam across the stream, and so form a storage lake, which will, it is believed, be capable of supplying the city with 175,000,000 gallons of water every twenty-four hours. This lake will be from 500 to 1,000 feet wide, about 20 feet deep on the average, and will extend up the Gunpowder a distance of about 5 miles through the most picturesque scenery, which is constantly changing, as the river and the valley through which it runs pursue a very devious course between ranges of precipitous, wooded hills, from where it leaves the open country near Meredith's Ford bridge, which forms the head of the lake. To facilitate operations, a road 10 miles long, about 30 feet wide, and about 10 above the intended level of the lake, has been cut in the sides of the hill on each side, which will no doubt be utilized hereafter as a pleasure drive by the lovers of beautiful scenery.

At the lower end of the site chosen for the lake, two hills jut out into the valley, leaving but a comparatively narrow place, of which advantage is taken to form a dam which will raise the water about twenty feet above the natural level of the river. In one of these hills is the mouth of the tunnel, hereafter referred to, from the side of which a dam will be built having an overfall of 300 feet and a wing of 190 feet, that will extend into the opposite hill. This dam will be of the most substantial character, of heavy stone laid in hydraulic cement. The stone work will be 31 feet high and about 65 at the base, having its foundation on the solid rock; and it is estimated that about 20,000 perches of stone will be required for this part alone. The face of the overfall will be built of large blocks from three to four feet in depth; and to prevent any undermining, an apron is to be cut below the overfall resting four feet below any of the other foundations. The other side of the dam will be protected by a backing of 165 feet of puddle clay, gravel, and riprapping. The parapet walls will rise 12 feet above the overfall, and will be level with the floor of a gate house that is to be erected at the tunnel end of the dam. At the gate house begins the tunnel, which is to carry the water to Lake Montebello. This tunnel is nearly seven miles long—36,510 feet—and is therefore the longest in the country. The bore is circular in shape and is 12 feet in diameter. Over five miles of it will be through hard gneiss, which is being cut with drills driven by manual labor, as the contractors think that, owing to the comparatively small area of the tunnel, the power drills are not economical enough to pay them for the cost of the necessary machinery. A portion of the tunnel is being cut through softer material—a kind of limestone, that crumbles into powder by the force of the explosion when blasted. This part of the tunnel will have to be bricked; but where the gneiss occurs, the brickwork will be dispensed with, except in some localities where there are bad breaks and crevices in the rock, and at the bottoms of the shafts which will, when the tunnel is completed, be arched over with masonry 6 feet thick, to withstand the immense pressure of the loose earth filled in above.

To facilitate the operations in the tunnel, fifteen shafts, from 65 to 300 feet deep, have been sunk, most of which are down to grade; and in some of them considerable work has been done on the tunnel. But owing to the hardness of the rock for the larger portion of the distance, very fast progress cannot be made—only about a running foot of tunnel per shift of 12 hours, or two feet per day, as in tunneling night and day are alike so far as work is concerned, the only light in either case being that obtained from the small lamps attached to the miners' hats. As before stated, the contractors employ manual power for drilling, which, in the hard work, is done by task work—thirteen feet per shift being the miner's task. The holes are bored 30 inches deep, and an eight ounce cartridge of giant powder (nitro-glycerine and sawdust) is used in each hole, at which rate about 7 lbs. of powder, at 40 cents per lb. is used for each running foot of hard rock tunnel, making for the five miles through the gneiss nearly $74,000 for explosive alone, to say nothing of that used in the other portions of the work.

The shafts are from 8 x 17 to 8 x 20 feet inside the timber work, which, when used, adds about 30 inches to the above figures; and as fast as they are completed they are fitted with improved safety cages to prevent accidents from the hoisting mechanism; but they have only the ordinary tipping bucket until the shaft is down to grade. The exhaust from hoisting engines is utilized to create a draught in a pipe, the mouth of which is near the heading, and by this means ventilation is secured in the tunnel.

In the limestone portion of the tunnel, between shafts 1 and 2, the stratum makes an eccentric dip, leaving a "pocket" of mud which, as the miners were working towards it, suddenly ran into the tunnel, overwhelming and suffocating one poor fellow who had been driven by it against the timbers; but the remainder of the workmen managed to escape. In this, as in some other sections, the water forms a great hindrance to operations, a spring being found here which keeps a steam pump of a capacity of 200 gallons a minute constantly at work, while about the same quanity of water percolates through other crevices in the rocky sides of this section of the tunnel and has to be removed by another pump of the same size. The same trouble occurs in other shafts, especially No 5.

To make the necessary observations required to properly line and level the tunnel, a straight line has been made over the tops of the hills and through the woods, and three observatories have been erected for this purpose. As an instance of the great care taken by Mr. Martin in this matter, it may be stated that these structures are double, consisting of an inner tower (on which the instruments are placed) protected from atmospheric and other influences by an outer one, entirely detached from the other, on which the engineer stands when making his observations.

At the lower end of the tunnel is to be located a reservoir, to be known as Lake Montebello, which is being formed by damming up a valley admirably suited to the use to which it is being put. The upper and lower ends of the valley, forming the east and west sides of the reservoir, will be closed up with dams of stone and earth, 450 feet wide at the base and 100 feet at the top, with each end embedded in the hills at the sides, so that the greatest possible strength may be obtained; for this is one of the most critical pieces of construction along the whole line, and these dams will have to sustain the pressure of 600,000,000 gallons of water. The north and south sides of the valley, about 3,500 feet each, will form the other sides of the reservoir, which, when completed, will have the appearance of a natural lake, and will have a superficial area of about 80 acres and a depth of at least 30 feet. The sides will be finished with riprapping, and the top will be surrounded by a fine road 1½ miles long and from 60 to 80 feet wide, divided from the reservoir by a neat and substantial iron fence.

There being a stream running through this valley whose water is too impure to be used, a drainage tunnel, 2,870 feet long and of 9 feet diameter, had to be made to carry it away, which tunnel will also serve to take off the surface drainage, and to empty the reservoir, should it be required. From this reservoir, another tunnel, 2,600 feet in length and 12 feet in diameter, is now in course of construction. This tunnel is cut through soft material, and therefore requires strengthening with brickwork laid in hydraulic cement. Where the tunnel is of the right character, the top arch is three bricks thick and the invert below the spring line two bricks, with a proportionate backing from 18 to 24 inches above the

spring line built in against the timbers or the rock wall of the tunnel. In the soft places there is an additional ring of brickwork added and the backing is proportionately increased. In all cases, the arch is packed over the top with clay well rammed in. The brick work in this, as in the main and drainage tunnels, requires to be done with the greatest care, as it has to stand not only the outside pressure of the immense weight of material above it, and in railroad tunnels, but also the internal pressure of the water within, which is always searching for weak spots to break through, and it is therefore being done by the day. It is estimated that about 12,000,000 bricks will be used in all the tunnels.

One portion of this tunnel passes beneath a well, the bottom of which is only four feet from the top of the tunnel; and yet the water of the well has not been drained, and it continues to furnish its usual quantity of water, notwithstanding that another well, 300 feet from the tunnel, was almost immediately drained and has now no water whatever.

At the end of this tunnel will be a gate house from which the water will pass into six pipes of 48 inches diameter each, by which it will be conveyed to the city limits, and there connected with the present system of mains for distribution throughout the city.

Along the line of the work have sprung into being several temporary villages for the miners and laborers, showing styles of architecture that one would hardly expect to find so near a great city, varying from the tolerably comfortable offices of the contractors to that of the squalid log huts of the negro laborers on the storage lake, with a single room that is half below ground and half above. Many drinking shops have also been built on the line, or rather as near to it as they can be built (for the engineer will not allow them on the city property), in which the men squander their hard earnings after each pay day, and so unfit themselves for their labor as to cause no small delay to the progress of the work.

Unlike the officials of some other cities that may be named, those of Baltimore appear to have a fashion of completing their public works without exceeding the appropriations for them. This was the case with their city hall, inaugurated a year or two ago, and it appears as if it would be the same with the water works. The amount appropriated for this purpose is $4,000,000; but the engineer in charge, who is doing his best to cut down the expenses all he can without depreciating the quality of the work, thinks the whole improvement can be completed at a cost of very little, if any, over $3.000,-000. About 1,500 men are employed—common laborers getting $1.25 per day and miners $1.50. It is expected that the whole work will take about three years to finish, and Baltimore will then have a natural flow through the tunnel that will supply it for generations to come with all the water for ordinary purposes that can be used or wasted, as the river at the point tapped is 170 feet above mean tide, and consequently will give water to nearly all the houses in the city, except in the extreme northwest section, for which the water will still have to be pumped into a high service reservoir.

Mr. Martin is assisted by Mr. C. P. Manning, consulting engineer, W. L. Kenley, chief assistant, and seven resident engineers, Messrs. R. B. Hook, W. R. Warfield, C. O. Swan, C. T. Manning, O. H. Balderston and C. A. Hook, who are named in order of the work they have in charge, beginning at the storage lake. The contractors, also named in the same order, are Messrs. Condon, and Co., Fenton and Allan, Bruce and Patterson, L. B. McCabe and Brother, J. Donohue and Brother, and J. E. Eschback.

From this cursory sketch, some idea of the magnitude of the work in which the city of Baltimore is engaged may be obtained—a work alike honorable to the public spirit of her citizens and the gentlemen engaged in its construction.—*Scientific American.*

ON THE CONSTRUCTION AND WORKING OF THE ST. GOTHARD RAILWAY.*

BY G. PACHO.

The execution of the St. Gothard Railway, the design of which was to place Italy in direct communication with Eastern Switzerland and with western Germany, is opposed by serious difficulties. A loss of at least £4.-000,000 sterling is threatened, according to the calculations of the last-appointed Engineer, M. Hellwag. The operations have been suspended, the staff discharged and only the works of the great tunnel are being carried on. From the report of the directors of the company it is possible to form an idea of the cause of the mischief.

After a long contest between the promoters of the three Alpine lines of St. Gothard, Lucomagno, and the Splugen, the St. Gothard valley was finally selected as the line which appeared to promise most advantage at the least cost.

By an agreement dated the 28th of October, 1871, the delegates of Switzerland, Italy, the North German Confederation, Wurtemburg, and the Grand Duchy of Baden, united their efforts to overcome, by means of a Swiss railway through the St Gothard pass, the obstacle, presented by the Alps, to the junction of the railways of Central Europe with those of the Italian peninsula.

After an examination and survey, the details of which occupy two volumes published by the Italian ministry, it was estimated that the total cost of the undertaking, including the approaches, the tunnel, and the complementary lines, would amount to £7,480,000. In order to attract private enterprise to the work it was considered necessary that the sum of £3,000,000 should be subscribed by the states interested in the communication, as an absolute gift, in which case it was anticipated that the remaining £4,480,000 might be obtained by subscription. The estimated revenue was given at £252,-480 per annum. It appears, however, that the preliminary surveys were far from accurate. The International Commission contented themselves with prescribing that the works should be executed with the utmost economy.

The St. Gothard Railway Company was formed on the above basis. The capital was subscribed. A contract was entered into with M. Favre, the contractor for the Mont Cenis tunnel, to execute the tunnel under St. Gothard, and the work was commenced. The network of railway which it was intended to construct amounted to a total length of 164 miles. Soon afterwards, however, important deficiencies were remarked in the estimates. In April, 1874, the Chief Engineer, Gerwig, presented a further detailed estimate of the cost of construction, which exceeded by about £1,168,000 his estimate of 1872. M. Gerwig resigning his post, was succeeded by M. Hellwag, who considerably modified the plans of his predecessor, and arrived at an estimate exceeding that of the International Commission by £2,412,440, making the total cost of the line amount to £9,892,440. The chief difference in these estimates arose in the approaches to the tunnel. M. Hellwag's plan was based on the principle of keeping the line near to the bottom of the valleys, so as to maintain communication, at the stations, with the existing roads, and then to ascend the scarp of the mountains, at the entrance of the tunnel, by a series of zigzags, or, as he called them "helicoid volutes," constructed at the most appropriate points. It was expected that this method would prove the cheapest. The result of the detailed plans was however, this increase of £2,412,440 on the former estimate.

Without entering into the details of this considerable difference, the author proceeds to point out that the cost of the two lines in the valley of the Ticino, now open, namely the Biasca-Bellinzona-Locarno, and the Lugano-Chiasso sections, which had been estimated by the International Commission at £742,400, amounted, or would amount when complete (after allowing for a loss on working in the first instance, before the completion of the entire line), to £2,064,000; a difference which, in the opinion of the members of the General Committee of Direction of the St. Gothard line, is "truly colossal."

The reasons for this extraordinary excess, according to Signor Pacho, become apparent on a perusal of the report of M. Hellwag; who is accused of having entirely lost sight of the real object of the railway, that is to say, the formation of a route for transit from Italy to Germany. To give an idea of the scale of magnificence adopted, it is mentioned that the provision for sidings and accessory lines on this section, which had been calculated by the International Commission at 20 per cent. of the length of the mileage, amounts, according to M. Hellwag's plan, to a length equal to that of the total mileage of the section. This explains how an estimate of £742,000 has been swollen to one of £2,-064,000.

The report of the directors, drawn up under these circumstances, remits to the Federal Council of Switzerland the task of entering into fresh arrangements with the other interested states, for the purpose of raising the additional funds now found to be necessary for the completion of the line. To meet the responsibility of the directors, it is calculated that at least the original subscription, or free gift, of £3,000,000 must be increased by the further sum of £4,094,840, a demand which appears to the directors difficult to urge.

To give an idea of the differences shown by the revision of the estimates, the following particulars are cited. The estimate of the International Commission for the cost of the general administration, comprising the expenditure incurred in raising the capital, and the expenses of the central administration, was £74,156. That of M. Hellwag, in 1876, amounted to £258,880 The cost of surveys, in the former estimate, was set down at £100 per mile, amounting to £26,540. In the latter it stands at £268 per mile, giving an amount of £74,200. For the purchase of land the first estimate allowed £179,760; the second, £456,960. For the station at Lucerne, and the fourteen sections of line on the Swiss side of the Alps, the estimate of the Commission was £3,840,404; that of M. Hellwag £6,795,-124. For the tunnel itself the additional cost was only 2½ per cent. For the three sections of line on the Italian side, 17½ per cent. was added to the former estimate. The general account of cost, according to M. Hellwag, was as follows:

Reimbursement of preliminary expenses..	£20,200
Raising capital	244,800
General administration	138,472
Interest to opening of line.....	1,309,800
Engineering (technical direction)	459,968
Actual construction	9,401,620
	11,574,860
Estimate published by Italian Government.	7,480,000
Deficit.....	£4,094,869

To this sum, however, a considerable addition has to be made for interest during the time occupied by the suspension of the works. As the total length of line composing the entire network was 164 miles, this gives a cost of £70,578 per mile, whereas the original estimate was £45,610 per mile.*

Starting from the above data, and considering that the deficit of £4.094,860 could not well be covered by the issue of shares or debentures at less than six per cent., and that any addition either to the capital raised, on the one hand, or to the time consumed by suspension of works on the other, must add to the final cost of the undertaking, there seems every reason, the author thinks, to anticipate that, without the aid of a considerable subsidy from the states interested, the deficit will amount to at least £4,400,000. It is possible that the original estimate was too low. But it was based on the experience previously obtained in the execution of Alpine lines, the prices of which had been adopted by the Commission as normal.

The remainder of the paper is taken up with a detailed examination of the economies which might be effected in the execution of the works; and by the substitution of steamers on the Lake of Lucerne for the construction of certain portions of the line. The gradients vary from 1 in 122 to a maximum of 1 in 26.77, the mean ascent from the station of Silencia, on the northern side, to that of Goschenen. On the Italian side the mean gradient is 1 in 28.65.

THE NEW YORK BORDER.

Capt. Patterson, Superintendent of the United States Coast Survey, has received a letter from J. V. L. Pruyn, the chairman of the New York Commission appointed

*Abstracts of Papers in Foreign Transactions and Periodicals. The Institution of Civil Engineers, London.

*The actual length of the St. Gothard Tunnel, which is not given in Signor Pacho's Paper, is 16,241 yards. The work was contracted for by M. Favre, on 7th August, 1872, at a price equivalent to £116 8s. per yard, to be completed in eight years. The last 4,781 yards of the Mont Cenis Tunnel were let to MM. Sommeiller and Grattoni at a price equivalent to £167 12s. per lineal yard. It was conjectured that the cost to the contractors did not exceed £74 per lineal yard. The preliminary estimate of the total cost of constructing the Mont Cenis Tunnel amounted to £2,600,000; which was at the rate of £194 per lineal yard. It is supposed that the actual cost amounted to £3,000,000, which is equivalent to £224 per yard; or £394,240 per mile. The cost of the Thames Tunnel was £1,127 per lineal yard.

to rerun the boundary line between the States of New York and Pennsylvania, in regard to the detail of an attache of the Coast Survey to perform the astronomical work. Several weeks ago Col. Worral, one of the Pennsylvania Commissioners, had a consultation with Capt. Patterson on the same subject, and it was this interview which led to correspondence between the Pennsylvania and New York commissioners. Capt. Patterson will promptly accede to the request of the commissioners when it is formally made, and will designate for the work one of the most skillful men of the service.

On the 12th of October, 1786, Commissioners Andrew Ellicott for Pennsylvania and James Clinton and Simeon DeWitt for New York, appointed for the purpose of running and marking a boundary line between the two States, to begin at the Delaware River on the 42d degree of north latitude, and to continue on the same parallel to the western extremity of the States, reported that they had finished 90 miles of the boundary extending from the Delaware river to the west side of the south branch of the Tioga river, and had marked the same with suitable milestones. One year later, October 29, 1787, Andrew Ellicott and Andrew Porter, Commissioners of Pennsylvania, and Abraham Hardenberg and William Morris, Commissioners of New York, reported that they had extended the line from the ninetieth milestone to Lake Erie, and that they had marked the line in a permanent manner by milestones, or posts surrounded by mounds of earth when stones could not be procured.

The observations and surveys were conducted under the directions of the eminent astrononomer and mathematician, David Rittenhouse.

The object of the resurvey authorized by the two States is to correct the line, which it is believed varies at many points from the parallel designated in the origin charter to William Penn as the limit of his proprietary possessions in the direction of the Royal Colony of New York. This, it is admitted, was not owing to lack of skill, but to the crude state of astronomical science at that time and the imperfection of the appliances used. Of late years there has been a very general resurvey of the boundary lines of the older States, and in some cases very serious errors have been discovered, and if the commissioners should finally determine to invite the Superintendent of the Coast Survey to designate one of his assistants to take direction of the surveying portion of the work, a thorough geodetic survey be made. The crudity of this branch of science a century ago will, it is believed, present a practical illustration of the difference between surveying on a plane surface and adapting the line to the curvature of the earth.

It would also be Capt. Patterson's object to gain another advantage from the opportunity offered, and that would be to measure geodetically the arc of the parallel. The expense of this portion of the work he would ask permission to defray out of the coast survey fund, and would make a continuation of the arc to the Hudson River, from which point to Cape Cod, also on the parallel of 42° north latitude, the data are now in the possession of the office. It is estimated by Capt. Patterson that an additional work of about 100 miles out of the funds of the coast survey, with the material on hand and the boundary survey, would enable him to complete an arc of parallel of 450 miles from Cape Cod to Lake Erie.—*New York Tribune.*

APPLICATION OF PHOTOGRAPHY TO TRIGONOMETRIC SURVEYING.*

Lieutenant Manzi, of the Italian army, has recently produced trigonometric surveys by the aid of the camera, which have obtained the approbation of the Ministry of War, and have been considered worthy of the support of the Topographical Institute.

If it be supposed that an observer be placed at the point of vision of a theodolite station, and that the rays of light converging from the distant points of view are intercepted and marked on a diaphragm, it is evident that the angular readings obtained to such points would be identical in their bearings with the objects themselves. The perspective indication thus obtained may be mathematically used by definition of the three following constants: (1) The horizontal line; (2) the distance from the optic centre to the diaphragm; (3) the position of the principal point of view. It is thus possible to construct a camera, geometrically arranged, with an object glass so ground as to minimise the area of observation, or to allow of the establishment of a differential equation of the curve of error. By such a camera, negative views of inaccessible ground can be faithsully taken, and the angles can be either plotted or calculated. By obtaining photographs of this description from properly connected points, intersections can be obtained, either graphically or by trigonometric calculation, in the same manner as by the use of a plane table or of a theodolite. The main obstacle which Lieutenant Manzi encountered arose from the fact that if the points of observation selected were so near as to be perfectly distinct, the triangles became very ill shaped. On the other hand, very distant points were with difficulty precisely determined. This was obviated by operating on small base lines (from 400 to 800 yards) and estimating the primary triangulation by a telemeter (like that of Nolan). The application of the photographic details to the points thus fixed was then simple. In the case of inaccessible mountain country the advantages thus to be obtained are obvious. It is also a matter of no small importance as regards military recognisance. The results obtained in the course of the present year are said to be highly satisfactory.

CORRESPONDENCE.

BOSTON, *May 15th, 1877.*

Editor ENGINEERING NEWS:

SIR.—One of your readers has had experience with "tar and gravel concrete" street gutters, with only 0.1 ft. available fall in 100 ft., and recommends them to Wm. Johnson, City Eng'r, of Dallas, Texas, correspondent in your paper of 12th inst., and to others similarly situated.

C. H.,
Civil Eng., (one time Supt. of Streets.)

NEW ORLEANS, *May 15th, 1877.*

Editor ENGINEERING NEWS:

SIR.—In your issue of May 5th, 1877, I notice an article and map describing and representing the "drainage of the city of New Orleans, by F. T. Hardee, City Surveyor." With all due deference to Mr. Hardee as a map copyist, permit me to inform you that the system of drainage works were in course of construction nearly three years previous to Mr. Hardee becoming City Surveyor, which was in December, 1874, and about seven months after the city purchased the dredging machinery and suspended the works. So much for the prospective drainage of New Orleans. Mr. Hardee never designed any portion of the drainage system, and during the time he administered it, followed the system as indicated upon my plans.

In the October, 1875, number of the "Sanitarian," published in New York, the same map and article appears without credit, which is due to each other in the profession, the profile from river to lake was also a matter of record in the surveyor's office when he assumed charge. Accompanying this you will find lithograph copies of drainage map, lake protection levee, and oscillations of river and lake waters, and respectfully request that you publish this communication at an early date and oblige, Yours truly,

W. H. BELL C. E.

WAUKEGAN, ILL., *May, 17th 1877.*

Editor ENGINEERING NEWS:

SIR.—I see in the last number of the NEWS, a communication from G. C., Galesburg, Ill., concerning the correct method of re-establishing a lost ¼ Section corner. He states that on the line between Sections 24 and 25, in a certain Township, the ¼ corner is lost, and that "field notes" describe the corner as being 40 chains and 70 links from the West corner, of the Section, and 39 chains and 30 links from the East corner. The two together measure 40 chains, just full, measure, (although seldom occurring on East and West lines in Government surveys.) The fair presumption is, that the field notes have been wrongly copied. The following queries arise: 1st. Are the field notes to which he refers *correct copies* of the Government Field Notes? 2nd. Or are the distances taken from, the *Government Plat*, instead of the notes? 3d. Has G. C., had access to the *running* notes of the Government Surveyor? 4th. If he has access to certified copies of both Government notes and Government plats, has he compared the two, to see if they agree. In the first place, the Government Surveyors are required to place ¼ Section corners, equi-distant between Section corners, except in the tiers of Sections along the North and West lines of Townships. Then again, there are sometimes discrepancies between the plats and written notes, in which case the written notes are the better evidence. As plats are made from the notes, the law undoubtedly is, that the Government corners must remain as set by the Government Survey, although there may have been a mistake. The question is how to ascertain the original position of a lost corner. And in doing so, the best available evidence should be used. And witness trees, or other comparatively durable objects taken as witnesses, are usually the best evidence. The careful Surveyor will use all available kinds of evidence. In my practice I find the most satisfactory evidence by digging, to ascertain if a stake has ever been driven. On hard land that has never been deeply plowed, dug or washed, the stake-hole will show. Take a spade, or any other *sharp* instrument and carefully shave the ground horizontally, and as soon as the hard soil is reached, the stake-hole will show like an auger-hole through a board. The hole will be filled with soil of different color; and of a softer texture. These hints may be of use to G. C., or some other Surveyor.

H. WHITNEY.

ACTIVE preparations are going on for the immediate commencement of the long-projected work of draining the Zuyder Zee. A dam 40 kilometres (24 miles 1540 yards) long, and 50 metres broad at its base, is to be carried across the gulf, built up to a height of half a metre above the ordinary level of high tide. Upon this pumping machines of 10,000 horse-power will be erected, capable of pumping up from the enclosed sea, and discharging on the outside of the dam, 6,500,000 cubic metres of water daily. Taking the average depth of the water at 4½ metres, it is estimated that the work of pumping will be completed in about sixteen years from its commencement. The total cost of reclamation is set down at 335,000,000 francs; but huge as this sum is, the undertaking is confidently looked upon as likely to prove a most remunerative speculation. The success of the scheme will add to the kingdom a new province of nearly 500,000 acres in extent. Judging from previous experiences in connection with the Haarlem Sea, it is reckoned that at least 176,000 hectares of the land thus won will be applicable to agricultural purposes, which, at an average value of 4,000 francs only per hectare, will richly repay the enterprise and treasure lavished on the gigantic undertaking.—*The Farmer.*

From the Institution of Civil Engineers, London:

Abstracts af of Papers in Foreign Transactions and Periodicals. Session 1876-77. Part 2.

We have received from Messrs. Fauth & Co., of Washington, their new illustrated catalogue of the Astronomical and Surveying instruments manufactured by them. It contains much valuable information on the subject of instruments and is profusely and excellently illustrated. It will recommend itself to all who send for it.

The following is the contents of *Harper's Monthly* for June, most interesting as usual:

Contemporary Art in Germany—S. G. Benjamin. With Twenty Illustrations. A Dream-land City—A Poem—Mrs. Frances L. Mace. The Androscoggin Lakes—Edward Abbott, With Nineteen Illustrations. The Niebelungen Lay—Leda M. Schoonmaker. With Eight Illustrations by Fredericks. Erema; or, My Father's Sin—R. D. Blackmore. La Festa dello Statuto. A Poem—William Gibson. The Wheeler Survey in Nevada—William H. Rideing. With Eleven Illustrations. Gibraltar—George M. Towle. With Three Illustrations by amuel Colman. Moses Clymer's Business—Marc. E. Cook. With Two Illustrations. An Order for a Cameo. A Poem—Fannie R. Robinson. Bird's Nests—H. D. Minot. With Five Illustrations. The Professor's Victim. A Story—Mrs. Frank McCarthy. Popular Exposition of Some Scientific Experiments. Part IV.—Dr. John W. Draper. With Six Illustrations. A Woman-Hater. Part XII.—Charles Reade. A Tear. A Poem—Harriet Prescott Spofford. Garth. A Novel. (Concluded.)—Julian Hawthorne. Editor's Easy Chair: Editor's Literary Record: Editor's Scientific Record: Editor's Historical Record: Editor's Drawer: A Short Sermon—A comical Compliment (Illustrated).

RAILROAD NOTES.

The Lafayette, Bloomington & Munci R. R., Ill., will hereafter be known as the Lafayette, Bloomington & Mississippi R. R., and will be under the general management of General E. H. Waldron.

California has 1,853 miles of railways, of which 176 miles, or nearly one-tenth, are of the narrow gauge. The narrow gauge is especially suited to the rugged profile of much of this State, and a number of that class are under way or projected.

At a meeting of the Brooklyn Board of Aldermen on the 14th inst., permission was granted to the Brooklyn City Railroad Company to run steam cars on Third avenue, from Twenty-fifth street to Fort Hamilton. The noiseless locomotives will be placed on that line immediately.

During last winter the right of way was cleared for 20 miles northward from the present terminus at Clayton, Wis., on the North Wisconsin R. R., and work has now been begun on the grading. Contracts have been let for the first 10 miles, to be ready for the rails by Aug. 1, and considerable force is now employed.

The Toronto *Leader* of the 16th, inst., says, it has it on undoubted authority that the Grrnd Trunk and Great Western Railways have finally amalgamated. The headquarters of the Grand Trunk Company, their workshops, fitting departments, etc., will be removed from Montreal to Toronto.

It is proposed to build a branch leaving the Dorchester & Delaware, R. R., near Cambridge, Md., and running south through Lakeville to Bishop's Head, 22 miles. Dorchester County has voted $75,000, leaving about $25,000 to be raised by stock subscriptions. The branch is expected to secure some local business and a large traffic in oysters and fish.

Some steel-headed rails were laid down upon the East Bavarian railway in 1869 at places where the gradients are 1 in 100 and the curves of 14½ chains to 26 chains radius. The percentage of renewals to the close of 1872 was as follows: 1869, 0.60 per cent.; 1870, 0.00 per cent.; 1871, 2.65 per cent.; 1872, 0.00 per cent.; total, 3.25 per cent. A similar calculation applied to steel-headed rails laid down on the Bavarian State Railways shows renewals to the extent of 2.23 per cent.

It has been decided to equip the Boston, Winthrop & Point Shirley R. R. with twenty-pound per yard angle rails, bolted to substantial wooden stringers, which are placed on ordinary ties. It is claimed that these rails will prove far superior to the forty-pound per yard T rails, as they not only prevent accidents proceeding from broken rails, but make also a large saving in the cost of construction. The angle rail is said to be adapted to standard as well as narrow-gauge roads.

At the annual meeting of the Hamilton & Northwestern R. R., in Hamilton, Ont., May 1, the President reported that arrangement had been made to extend the Lake Erie Division from Jarvis to Port Dover, 10 miles, this year. The Northwestern Division was opened in February from Hamilton to Georgetown, 35 miles, and 29 miles more, from Georgetown to Barrie, are under contract to be finished this year. Work is soon to be begun between Clarksville and Glencairn.

At a meeting of the Board of Directors of the Northern Pacific Railroad Company, the Finance Committee reported adversely to placing a mortgage on the line of road now in operation on the Pacific coast. A resolution was passed requesting the stock-holders to be informed that in view of the increased and increasing business of the road, the Board was of the opinion that all the money necessary for the completion of the branch into the coal fields of Payslip valley can be had without resorting to mortgage.

A competent engineer, accompanied by a corps of assistants, left Salem, Ill., May 14, for the purpose of surveying the route of the proposed extension of the narrow gauge road from Phillips' Corners to Wingville. The original intention was to build the road from Platteville, the present terminus, through Washburn to Wingville. That plan has been abandoned, owing to the unfavorable lay of the land. A construction train will be put on the line as soon as the survey is made, and by fall the entire road will be completed. The plan of building a narrow-gauge road from Lancaster to Phillips' Corners, tapping the Galena & Southwestern Railroad at that point, is favorably talked of.

A proposal is made to lay a street-railway track of the following description in San Francisco: "The rail, it is proposed, shall be twenty inches wide at the base and three at the top, over which the car-wheels glide. The rail is hollow, and designed to inclose the large gas and water mains side by side on the base, the connections to be made from them into the upper stories of houses along the route. Over these mains another tube incloses the telegraph wires. The rail is to be supported on large posts fourteen feet high, and placed at distances of fourteen and twenty feet apart. The posts are to be secured in the sidewalks, at the curbs, and will serve as hitching posts, and, with proper connections with the water-mains, hydrants may be attached to them." We have only one suggestion to make. Another tube should be added which should combine the functions of a pneumatic-dispatch tube and a clothes-line, and when worn out can be worked up into pop-guns and spy-glass frames.—*Railway Age.*

Pacific Railway construction is to be begun at once in Manitoba, one of the contractors having been ordered to grade and lay the track on the branch line between Winnepeg and the Canadian Pacific main line, which is located some miles to the north of that town. It was announced in Parliament that the whole of the Pembina branch, which was graded a year or two ago, when it was necessary to give the Manitobans some relief in consequence of the grasshopper plague, would be completed at once, the track laid and rolling stock supplied. The terminus of the American road is as yet some fifty or sixty miles from the boundary, and there will be very little for the Canadian branch to do until a junction is effected. But the Manitobans believe that if the Canadian branch is completed, the American company will be stimulated to secure the junction, and extra traffic for their line, by building the necessary link, and the Government have acted on their representations in deciding upon their present policy in regard to the branch.

The *Engineer*, of London, gives an account of the "highest authentic instances of high railroad speed" on record. Brunel, with the Courier class of locomotive, ran thirteen miles in ten minutes, equal to seventy-eight miles an hour. Mr. P. Stirling, of the Great Northern, took, two years back, sixteen carriages fifteen miles in thirteen minutes, equal to seventy-five miles an hour. The "Great Britain," "Lord of the Isles," and "Iron Duke" broad-gauge engines on the Great Western Railway, have each run with four of five carriages from Paddington to Didcot in forty-seven and a half minutes, equal to sixty-six miles an hour. The new Midland coupled express engines, running in the usual course, have been timed sixty-eight, seventy, and seventy-two miles an hour. The 10 A. M. express on the Great Northern from Leeds has been timed, and found mile after mile at the rate of a mile in fifty-two seconds, or at sixty-nine and two-tenths miles an hour. The engines used are Mr. Sterling's outside cylinder bogie express engines, the load being ten carriages.

The sundry civil appropriation bill, passed at the last session of Congress, contains a clause appropriating $25,000 for continuing the survey of the Mississippi river and its tributaries, with a view of determining the proper method of reclaiming from overflow the alluvial lands of the Mississippi delta, and the chief of engineer corps has directed General Comstock, the officer in charge of the work, to expend this money with a view to the construction of levees, particularly in conformity with the report of the commission, consisting of General Warren, General Abbott, Captain Benyuard, of the engineer corps, and Jackson E. Sickles and ex-Governor Paul O. Hebert, civil engineers. These surveys are essential to determine the exact location, dimensions and cost of the levees. Their estimated cost is over $300,000, They will return all matters relating to the river beds, such as heights of the banks and places where caving is taking place, or otherwise, and the past changes, as far as can be made out. Level lines will be run with the greatest care, so as to determine the slopes of the water surface, and of the land and the elevation of high water marks.

At a meeting of the stockholders of the Northern Pacific R. R., held at New York, on the 9th inst., Mr. Stark, the Vice President, said the road was in excellent condition throughout, and had never been doing a better business than during the present year. Mr. C. Tower, of Philadelphia, for this board of directors, reported adversely on the proposition to put a mortgage on the western end of the road, in order to build the proposed extension from Kalama to Portland, Ore. All expenses to be incurred on the western end would be provided for without the mortgage. It was also the opinion of the board of directors that all the money needed for the completion of the branch into the coal fields of the Payallup valley can be had without resorting to a mortgage of any of the property of the company. Mr. George W. Cass, of Pittsburgh, considered the business of the company in Dakota in a more promising condition than ever before. He offered the following resolution which was adopted:

Resolved; That the stockholders deem it to be to the interest of this company to promote and secure the building of the line of R. R. from Sauk Rapids to Brainerd, a distance of about 60 miles, and approve, ratify, and confirm the action of the President and directors in subscribing 501 shares, of $100 each, being a majority of the stock of the Western Railway company, of Minnesota, understood to build said road.

2. That the directors are authorized, if necessary, to secure such construction and to lease said road when completed, at a suitable rental, such as shall cover interest on the sureties issued to construct the same.

The directors were instructed to ascertain the cost of building the Road from Bismarck west into Montana territory, and to propose a plan for providing the means for this purpose, which they will present at the next meeting of the stockholders.

FLORIDA NOTES.

A railroad about 25 miles long has just been located from Thomasville, Ga., to Monticello, Jefferson, Co., Fla., and Chief Engineer, Chas. F. Smith, says, construction is to commence at once. The R. R. from Lake Harris to Lake George in Sumter and Orange counties is all graded and the rails will be laid soon. A large traffic in oranges is expected. It is about 25 miles long

The railroad from Waldo, on the Florida R. R., to Tampa, about 160 miles, is graded the first 32 miles from Waldo to Orange Lake, Marion Co.

A railroad is chartered from Leesburg, Sumter Co., to Hickory Bluff, on Charlotte Harbor, Mannotee Co., 130 miles. A railroad is proposed from Live Oak, on the Florida, Atlantic & Gulf R. R., through Gainsville on the Florida R. R., to Leesburg, to connect with the last mentioned road about 126 miles; work was to have been begun on the railroad from Leesburg to Charlotte Harbor at once, but the Governor vetoed the bill granting certain State lands. A short-sighted act, for this State needs railroads and could better afford to have them at most any price than not to have them. The Governor did the same thing on the railroad from Sand Point, Valusia Co., Indian river to the St. John's river. This road, about nine miles long, is partially graded, the bridges built, and sleepers and timber all cut and on the line.

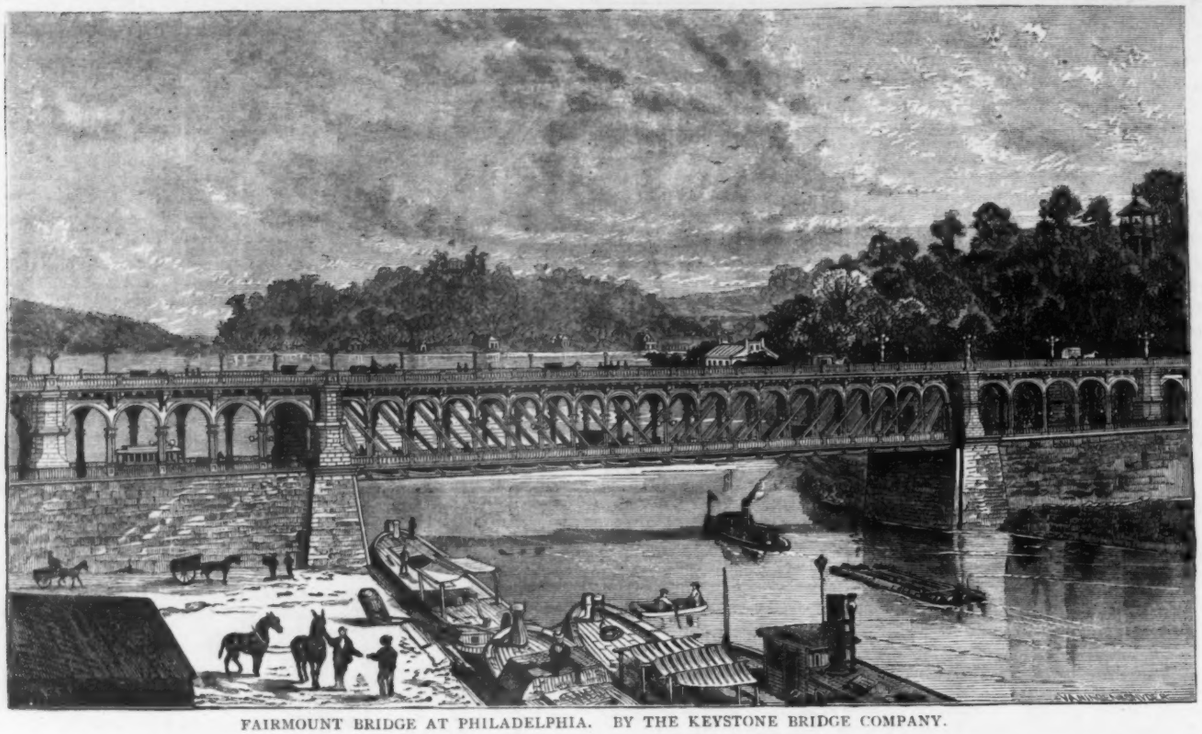
NOTES.

The Governor of New York State, has stricken out of the Supply bill the entire appropriation of $1,000,000 for a new capitol at Albany, and thirty-six other items representing an aggregate of $500,000 in addition.

The water power of Niagara Falls, known as the one-mile reservation, granted in 1806 by the State of New York to Judge and Gen. Porter, was sold at auction recently, subject to $60,000 of encumberances, to the wealthy firm of Messrs J. F. Schoellkopf & Son, of Buffalo, N. Y., for $71,000.

Justice Gilbert, of the Supreme Court, Kings county, New York, rendered a decision on the 14th inst. in the matter of the application made in behalf of A. S. Barnes and other property owners on the line of Atlantic avenue, for a permanent injunction prohibiting the Long Island Railroad Company from using steam on that thoroughfare. The case was argued about two weeks ago. The Court denies the application, with $10 costs. Work will now be pushed forward on the road.

The buildings for the Paris Exhibition of 1878 are growing rapidly. On the Champ de Mars the foundations are laid. The angle pavilions, which are of masonry and fifty feet high, are ready for the iron domes that are to cover them; and the walls of the central gallery, which is likewise of masonry, and intended for the fine arts exhibition, are almost finished. The piers of the rest of the building are ready for the superstructure of iron and glass. On the Trocadero, in spite of the great difficulty of laying the foundations on the hill undermined by quarry-galleries, the two elliptical wings are built, the substructures of the great towers are laid, and the masonry of the central rotunda is finished Two thousand men were employed upon the works; and up to the 1st of April, 1,800,000 francs had been expended upon excavation and masonry; covering 158,000 cubic metres of excavation, 30,000 cubic metres of concrete foundations and 35,000, cubic metres of masonry. Six miles of pipes and sewers had been laid.



FAIRMOUNT BRIDGE AT PHILADELPHIA. BY THE KEYSTONE BRIDGE COMPANY.

NOTES.—(*Continued.*)

The new explosive, known as "Vigorite" is formed of nitroline, nitrate of potash, chlorate of potash, and cellulose.

It is understood that a new movement is on foot to erect another bridge over the Ohio river at Louisville, from New Albany to Louisville.

Wire ropes for mines, elevators, and the transmission of power are now being made of the comparatively new alloy, phospor bronze. These ropes are said to retain their pliability after long use, and to resist the action of the corrosive waters found in mines.

A tunnel through the Pyrenees will place France and Spain in railroad communication by the 1st of January, 1878. The work has been several years in progress, and will save twelve hours of tedious diligence riding between Perpignan and Barcelona.

The City of Bridgeton, N. J., has just commenced the building of new water works. The works will be on the reservoir plan, with steam pumping machinery of not less than one million gallons per day. The water will be taken from East lake. Pipes of 16, 12, 10, 8, 6, and 4 inches diameter will be laid in all the principal streets. Isaac S. Cassin, of Philadelphia, is the engineer in the construction of the works.

The preliminary studies for boring the great tunnel of the Simplon and making accession lines are now in course of execution. The plans and measurements have been completed in the offices at Lausanne. The line commences at Brigue, which will thus become the international station, to enter the tunnel, which will have a length of 18,340 metres. The end of the tunnel will be near d'Isella, and the line proceeds from there to Bombo d'Assolla. The total length of the line will be 46,900 metres. Near Bombo it will rejoin the old works, the Italian line continuing to the station of Arona. As far as the village of Crevola the line follows the left bank of the Boveria, but crosses it there on a large viaduct.

Peru contemplates an imitation in her silver mines of the Sutro tunnel, which for many years has been in the process of construction for the drainage of the Comstock lode, in Nevada. The famous silver mines of Cerro de Pasaco, in Peru, have, since their first discovery, yielded silver estimated at $500,000,000 in value. This enormous sum was realized in spite of the unfaithful working and of crude systems that did not produce anything like the amount the ore was capable of yielding. The projected tunnel, by draining the mines, it is thought will restore their value and enable the miners to reach the richest ores. The project is the plan of Mr. Henry Meiggs, the famous American railway builder of Peru, and if it is pushed with the vigor characterizing his Peruvian railway construction, it is likely to be successful.

FAIRMOUNT BRIDGE, PHILADELPHIA.

We give above a view of Fairmount Bridge, Philadelphia. It is one of a number of similar cuts illustrating the useful work on Highway Bridges, by A. P. Boller, C. E.

We clip the following from the New Orleans Daily *Democrat*:

Col. Wrotnowski, the late Chief State Engineer, has submitted to the Governor a comprehensive and concise statement of all levee work that had been done in the State since the war, the statement showing the estimates as well as the number of cubic yards constructed in each levee, year by year, and the amount paid by the State to the Levee Company for such construction.

By that report it is shown that during the existence of the Board of State Engineers, since February 24, 1871, to date, there have been built six hundred and eighty-six levees, the total length of which is one hundred and eighty-nine miles and a quarter, which divided into cubic yards and put down to the different years, shows the following as the number of cubic yards constructed each year.

In 1871, 578,906 yards; in 1872, 2,557,761 yards; in 1873, 1,028,299 yards; in 1874, 737,952 yards; in 1875, 1,128,792 yards; in 1876, 773,193 yards; in 1877, 800,224 yards, and the amount provided for 1878, 230,248 yards, making the total bill during the existence of the Board of Engineers, seven million eight hundred and thirty-five thousand three hundred and seventy-five cubic yards—the amount set down for 1878 being, of course, approximated.

The approximate estimate for the current years shows that there are, above Red river, thirty levees, for which 2,196,000 cubic yards of earth is actually necessary, and below Red river there are ninety-two levees, for which 1,584,300 cubic yards of earth is necessary. On the Atchafalaya and Anglaise twenty-one levees require 187,800 cubic yards, and on the Lafourche five levees will require 22,000 yards; on the Ouachita three will require 52,000 yards and the fifty-eight levees on Red river will require 1,034,400 yards, this making a total of 209 levees in the State.

Col. Wrotnowski shows in his report that there have been constructed in the State since the war twenty million two hundred and sixty-two thousand seven hundred and fifty-two and thirty-nine one-hundredths cubic yards of levees at a cost of $10,972,441.47; and in his report, which is most complete, and made partly from the records gathered by himself, and principally from those made by the late Gen. M. Jeff Thompson, and giving, as it does, a complete history of the levees constructed in each parish, it would, if printed, make a valuable argument in support of Louisiana's claim for Federal aid in the construction of the levees.

CONTRACTORS' INTELLIGENCE.

The Wilson & Hughes Stone Co., of Cleveland, O., have received the contract for the entire stone work of the new Government building at Grand Rapids, Mich.

The Leighton Bridge & Iron Company, of Rochester, N. Y., are running on full time and employing about 150 hands. They are now engaged in filling a contract for six double track iron bridges for the Boston & Albany Railroad.

Morrison, Field & Co., of Buffalo, N. Y., have just received the contract for the construction of three iron bridges on the line of the Atchison, Topeka & Santa Fe R. R. The firm have also just completed two iron spans for the Missouri River, Fort Scott & Gulf Railroad.

Messrs. Clarke, Reeves & Co., of Philadelphia, have contracts for, and under construction, 40 spans, nearly a mile and a half, of iron bridges for the Quebec, Montreal, and Ottawa Railway.

The contract for supplying the rolled I beams, angle pieces, etc., for the Rock Island Arsenal, Illinois, was awarded to the Passaic Rolling Mill Company, of Paterson, N. J., and 130 Chambers St., New York City; the lowest bidders. The other principal firms who bid upon the same contract were: The Phœnix Iron Co., Phœnixville, Pa.; New Jersey Steel & Iron Co., Trenton, N. J.; and Carnegie Bros. & Co., Union Mills, Pittsburg, Pa.

For building and fixing Tank in Bellevue, Ohio:—For tank 24 feet high, 18 feet diameter, made of steel (known here as Otis steel) 3-16 in. thick for sides and ¼ in. bottom, placed in position on elevated foundation, thirty feet high; ⅝ in. rivets, hot, two inches center to center, two inch angle iron top and bottom, two coats paint, and to be made in good workmanlike manner and warranted not to leak. Buckeye Bridge Works, Miller, Jameson & Co. Proprietors, Cleveland, Ohio, was the bid accepted. It was $1368.00 for steel, and $1120.00 for iron. Lowest bid for 4-inch piping in position, 65 cts. per foot for cast iron and 50 cts. per ft. for wrought iron.

Bids accepted for erection of the Childrens' Home in Clark county, O.:—Petticrew & Bros., Springfield, O. Excavation, $280; Petticrew & Bros., Mason Work, $1,290; Russell & Sons, Springfield, Cut Stone Work, $1,035; Bryce & Webber, Dayton, O., Asbestine Stone Work, (award suspended), $1060; S. V. Boren, Dayton, Brickwork, $5,000; Geo. W. Cooper, Springfield, O., Lathing and Plastering, $993; Arbogast & Penfield, Springfield, Carpenter and Joiner Work, $5,688; Ackerson & Bros., Springfield, Slating, $425; T. B. Peet & Co., Springfield, Galvanized Iron Work, $1,108.80; T. B. Peet & Co., Tin Work, $325; Slevin & Hale, Dayton, Painting, Glass and Glazing, $831.38; Graham Jardine, Springfield, Plumbing, $899.86; Brooks & Kemper, Dayton, Steam Heating, $1,897. Total $20,833.04.

For the Excavation in the Harbor of Baltimore, Md.; J. H. Fenner, Albany, N. Y., 90,000 cu, yds. at 10½ c.: 160,000 cu. yds. at 12 c. M. F. Brainard, Albany, N. Y., 90,000 yds. at 10½ c.; 160,000 yds. at 12 c. G. C. Fobes & Co., Portland, Me., 400,000 yds. at 10¼ c.; 450,000 yds. at 12 c.; 250,000 yds. at 15 c.—on their own dump. American Dredging Co., Philadelphia, Pa., 90,000 yds. at 14 c.; 160,000 yds. at 11½ c. G. H. Ferris, Brooklyn, N. Y., 250,000 yds. at 10⅜ c. Morris & Cummings Co., New York, 850,000 yds. at 11 c.—on their own dump. Atlantic Dredging Co., New York., 150,000 yds. at 11½ c.; 250,000 yds. at 10¾ c.; 400,000 yds. at 10½ c.; D. Constantine, Baltimore, Md., 160,000 yds. at 9¾ c.; 90,000 yds. at 9⅞ c. 400,000 yds. were awarded to G. C. Fobes & Co., at 10¼ c., to be put on their own dump; 450,000 yds. awarded to the Morris & Cumings Co., at 11 c., to be put on their own dump; 250,000 yds. awarded to D. Constantine, at 9¾ and 9⅞ c., to be put on City dump. Dumping ground costs from ½ to ⅝ c. per yard, so that a bid of 10-c. material to be put on a place provided by contractor, is equivalent to one of 9½ c. when the city has to furnish place of deposit.

COMMITTEE REPORT OF THE OHIO ASSEMBLY ON THE ASHTABULA BRIDGE.

It is perhaps fortunate for Mr. J. M. Goodwin of Cleveland, that he did not carry out his intention of publishing a book on the Ashtabula Bridge disaster, for the report of the joint committee of the Ohio General Assembly, recently printed, is so full and satisfactory that it would have materially interfered with the sales of such a book. Through the kindness of Mr. Geo. S. Converse, a member of the committee on the part of the House, we have been favored with a copy of this report. It is very full, comprising in some 160 pages, the evidence of Messrs. Tomlinson, Rogers, Congdon, Stone, Collins, and Folsom, the expert testimony and reports of Messrs. Crehore, Gottlieb, Becker, Williams, and Howland, besides the report of the three engineers from Columbus, O., appointed to examine and measure the bridge. There accompany the pamphlet, strain sheets, templets of the I beams, plan, elevation, and very full details of the structure, and a sketch showing how the braces were chipped away at their ends. Those of our profession who continue to feel an interest in this matter, and who desire to possess this amount of information in a convenient form for reference, will find much that is valuable in the pages of the report.

The pamphlet also contains the draft of a bill "to secure greater safety for Public Travel over Bridges," which introduces very stringent requirements as to load, maximum allowable stress on the square inch, and inspection. In reading this bill we are strongly reminded of the reports of the committee of the *American Society of Civil Engineers* on the "Means of Averting Bridge Accidents;" we should not be surprised if those reports and the discussion which followed were referred to by the framers of this bill. As there is so much of interest to engineers in this bill, and as an abridgement would be nearly as long as the original, unless we left out some noteworthy features, we give it in full in another column.

MONTREAL MAIN DRAINAGE.

The city of Montreal is exercised about its drainage, and a scheme having been designed and work upon it already considerably progressed, it has been made the subject of much heated discussion in the city council and quite recently two reports have been made by Mr. Ansley the city surveyor, and at present the work has come to a stand still to await an examination and report by an outside Engineer. We quote from Mr. Ansley's reports April 11th and May 10th the following general remarks on the subject of city drainage.

Cities grow to considerable size before there is much attention directed to the subject of draining. Drains and sewers are constructed by proprietors, and afterwards by the Corporation, without any general system. In fact, it is a matter of growth and not of design. After a very large amount has been thus expended, an engineer is called upon to design new works that shall fit in with a great deal of what exists and which may be utilized, at the same time reconstructing what is too defective as to material, size or grade.

A plan may be prepared of the drainage of a whole city on the most perfect engineering principles, which, if carried out at all points, would be an admirable work; but the large amount already invested forbids the breaking up of every sewer to make another in conformity with such a plan.

The drainage of a city practically is first a patchwork, followed afterwards by a series of new works by way of amendment.

Mr. Ansley in his second report describes the topography of that portion of the city traversed by Craig street, along which it is proposed to lead the main drainage from the adjoining higher grounds by means of what is termed the Craig street Tunnel. He further remarks:

In the gradual building of a city, the inhabitants follow the natural drainage as their guide, seeking lower grounds from any point when they are building; hence, the sewers in this city were carried simply downwards, without any thought as to the difficulty of getting rid of the waters after it had been thrown into the valleys.

Some 30 or 40 years ago, so far as I can gather, a difficulty arose as to how to get rid of the water from the valley of Craig street, and then, for the first time, engineering skill was called to their aid by the people or City Council.

The system of natural drainage has sufficed heretofore, but now artificial drainage was needed, and, in view of the conditions existing, the design adopted was sound in principle. Craig street being a long line with slight grade from east to west, and for about half the distance practically a dead level, the length between Papineau and Victoria squares as divided into two parts, east and west of Lacroix street, and in each of these divisions there was made an artificial summit, so that there were, really, four sections, each having its own descent.

To fulfill this design, it was absolutely necessary to tunnel through the ridge under St. Mary street, and so make a new outlet to the river. This was formidable work at that time, but it was done. Now came also, in this connection, the era of brick sewers, although wooden ones were not abolished.

The sewers descending east and west from St. Lawrence street were of brick; those descending east and west from Panet street were of wood. Had these works been as well executed as they were designed in principle, it is probable that the present Craig street tunnel would not have been entertained. But later on two distinct causes arose inducing a change; the sewers in Craig street were not satisfactory; the tunnel under St. Mary street was very defective; to the east, the wooden sewers were at too slight a depth below the surface, too small, and with grades that allowed sediment to lie permanently on their flat bottoms. All these defects might have been overcome by reconstruction, but yet a more formidable objection existed. The public and the Council were strongly opposed to the issue of sewage into the harbor at Lacroix and McGill streets, and unless these issues were permitted, the whole design of Craig street had to be abandoned and undone.

Public opinion went further—it pointed out that the outlet should be at least as low down as the Current Ste. Mary, and the engineer's task became then, not to devise or defend the best method of drainage, but to accomplish an object under certain restrictions.

We have no long catch-water drains, as sewers running from west to east. The drainage of the hills is by sewers running down, like St. Lawrence and Bleury streets, while the long lines, like Dorchester and Lagauchetiere streets, are cut into feeders for the steep drains. The bulk of the water is let down on to the low grounds, and in view of the objection to letting it into the harbor in front of the city, hence the design of the present Craig street tunnel, the result of what has occurred before, and of the conditions that exist.

The tunnel will relieve the valley, and will also relieve the sewers which flow into it, and will be found practically efficient. There will be sediment of road grit in it, or any other insoluble matter which gets in, but this is common to all sewers. Its shape is particularly adapted for economical cleansing. The theories of sanitary engineers usually point out that all sewers should be self-cleansing, but it is well known that this very seldom, if ever, obtains in actual practice, When important works of main sewerage are entertained by a community, the general scheme should be prepared by their engineer and submitted for their discussion and approval; they should then, before finally deciding on the merits of the scheme, call to their aid the opinion of some outside authority in sanitary engineering works, after which the general principles should be adhered to, and the details carried out at that basis from time to time as required.

The most of the latter document is necessarily local in its character, but is throughout a clear presentation of the causes which led to the adoption of the scheme of drainage in controversy. The principal opponent of the scheme is Alderman Gauthier, and the following description of the meeting of the Road Committee during the reading of Mr. Ansley's report, indicates that the French element was characteristically lively.

We quote from the *Gazette* of May 10th:—

The report was read during a cross-fire of conversation, and little of the attention paid to it that is due a paper dealing with a subject of such importance, and coming from the engineer in whose charge the interests of the city's drainage are supposed to rest.

During the confusion of words that ensued the representative of the *Star* casually mentioned that he had had opinions against the Craig street tunnel from Messrs. Shanley and Hannaford, the well known engineers, and an opinion partially against it from Mr. Kennedy.

City Surveyor Ansley expressed his surprise at this, and said these opinions could not be officially given, as he did not think the gentlemen would give opinions on such a subject in a moment.

The *Star* representative said he had the opinions in writing, but had never used the names of the parties although the matter had been published.

The City Surveyor said if it was the wish of the city now to stop the work on the tunnel and procure the assistance of an outside engineer as to the merits of the case, no better authority in sanitary drainage could be found than Mr. Chesbrough, Chief Engineer of Chicago.

After some further conversation, a motion was carried to report to Council to stop the tunnel at Lacroix street, and to invite Mr. Chesbrough of Chicago, together with a resident engineer, to look into the whole matter of the Craig street tunnel; also, that Mr. Ansley be instructed to write to Mr. Chesbrough as to the arrangements.

After passing some other matters of routine the Road Committee adjourned.

THE ease with which photographs can be taken, and the moderate cost at which small views like those for stereoscopes can be obtained, enable one to possess pictures of important works in various stages of their growth. They of course show the false works, with the various appliances and expedients used in the construction, and, if well selected, enable one to readily understand the design. They are, in some respects, superior to drawings, unless dimensions are desired, and serve also as a very handy record of progress at different dates. The stereoscopic views of the arches over Charles River at Newton, Upper Falls, on the Sudbury river conduit of the Boston Water Works, are excellent examples of this sort, and will repay careful inspection.

THE Coroner's jury in the Rockford Court House disaster rendered their verdict on the 23d inst. After reciting the circumstances of the accident they give as the cause of the same—

1. The neglect of Henry L. Gay, the architect of the said building, to provide for the great amount of weight called for to complete the construction of said building according to plans as designed by him.

2. The want of care or prudence on the part of said architect in not giving special specifications and plans for the part or parts of the general plan required or expected to carry the weight in proportion to their superfices.

3. The fact that the Board of Supervisors failed to use that caution in examining the plans and specifications that the construction of a building of that magnitude would seem to require, and that they acted unwisely in not employing a competent architect to superintend the construction of the same.

CHICAGO at present presents but a poor field for sewer contractors and sanitary engineers. In view of the continued impecunious condition of the city treasury, the Finance Committee at the meeting of Council, May 14th, recommended that the sum of $79,000 only be borrowed for the purpose of completing the sewers already under contract. It is probable that this recommendation will prevail.

THE position which late developments in connection with the New York City, Rockford and Chicago Court Houses, proves the architects of these important structures to hold, is not very flattering to the profession. In these cases the architect appears to be but a draughtsman, useful only to make plans, tracings or such drawings as the contractor may want; he is nominally the source from which all instructions proceed, but really he cuts but a very small figure indeed, except to shoulder all the responsibility of mistakes and disasters. Gay sold some plans to the Rockford Committee, and that is about all he has had to do with the ill-fated structure which he designed, until called upon to protect himself against the possible charge of manslaughter; the daily press of this city is full of charges of "crookedness" against everybody connected with the new court house, and according to all accounts, architect Egan plays a very small "second fiddle" in its erection. The Chicago *Tribune*, referring to certain departures from the specifications, remarks:

It may appear surprising that Architect Egan, who has charge of the building, should allow any deviation from the plans he drew and the specifications he framed. But the trouble is that the County Board elected a Superintendent by the name of Handley; and, while he is nominally Mr. Egan's subordinate, he is practically his equal or superior. Mr. Egan has served upon Handley reams of notices and directions. Some of them Handley has observed; others he has disregarded, following only such as jumped with his peculiar notions. The unfortunate feature of this is that, while the responsibility is really divided, Egan will, if anything happens, be held responsible for whatever mishap there may be; and it would appear to be the wisest thing for him to either claim the control which belongs to him, or wash his hands entirely of the whole matter.

An architect is allowed to appear important and to give a great many directions during the occasional ten minutes' visits he may make to a city dwelling-house or warehouse in course of erection under his "superintendence," but after all his functions prove to be merely those of a draughtsman, and only too often they are about all he ought to have.

PERSONAL.

Among other changes in the faculty of the School of Mines, Columbia College, New York, is the appointment of PROF. WM. P. TROWBRIDGE, lately of the Sheffield Scientific School, Yale College, to be Professor of Engineering. The school is fortunate in securing so ex-

perienced an occupant of this important chair. He was born in Troy, Oakland county, Michigan, in 1828, graduated from West Point in 1848 with the highest rank, having assisted during the last year of his course in instruction in chemistry; and, for some years after, he served with much efficiency in the Coast Survey. He resigned in 1856 to accept the professorship of mathematics in the University of Michigan, but, within the year, at the request of PROF. BACHE, accepted a permanent appointment in the Coast Survey. During the war he did good service as a military engineer. At its close he became superintendent of the Novelty Iron Works, in New York city, where he remained until 1870, when he accepted the position of professor of dynamical engineering in the Sheffield Scientific School.

GENERAL C. B. COMSTOCK of the Engineer corps, has been granted leave of absence for one year with permission to visit Europe. It is understood that he will, if permitted by the belligerent governments, to visit the seat of war in the East.

ARTISTIC ENGINEERING.

BY HENRI J. HABER, M.S.C.E.

Engineering, restricted to its modern signification can not be traced farther back than about a century, previous to which time it formed no distinct science. The mason or carpenter built the bridge in which were embodied only material necessities; important works as those for water, and fine stone bridges were constructed by the well informed architect. We know and it is easily exemplified, that art is old, as old as man; not so engineering. We can define the latter as the art or science of constructions; it would follow then that engineering is dependent on art, but confining ourselves to our subject, we maintain that art is, in a measure dependent on engineering; we need only mention the printing press to illustrate, or the simple steam engine and note the great advantages accrued to art by them.

But returing again to the position of art assuming the foremost rank, we see, that in nearly all the older engineering works, art is given a most prominent position, and the science of engineering is but little heeded; we need only point to the highly ornamented bridges of Frankfort and Heidelberg, and note their scientific errors, nevertheless they are very much admired—simply for their art.

Engineering as observed above became a distinct science about one hundred years ago, and since then how has it been developed, and what engineers are there now? We can enumerate the civil, military, mining, mechanical, and many others, who claim the title, so that to become an engineer in the fullest sense of the word, one would have to be an universal genius. It is not our intention in this treatise, to speak of the general term engineering, but in connection with art, to consider civil engineering, or that branch which has solely to do with building of roads, railroads, waterworks, bridges and other public works. The term civil may properly include other branches, but for the sake of simplicity we will take it referring to the subjects above mentioned. The origin of this branch as a distinct science dates back to the development of the mathematical and natural sciences, and by the application of these the engineer has raised his branch to a science, making less use of the empirical. What greatly aids the work of the engineer to-day is, the methodical arrangement of past experience and observations. But observe now! Since the introduction of the scientific element into this branch, it will be readily conceded that there has been a gradual dropping out and off, as it were, of all artistic elements. It can be easily seen that the engineering of to-day in its so highly scientific development, has but little to do with art, so also in books on the subject do we find but little reference to art.

It is true that engineering does sometimes impair the beauty of a scene; as for instance, the deep cutting of a roadway impairing the harmony of a landscape, or the straight line of a corrected river impairing the picturesqueness of the meandering stream. But take works above the ground, consider bridges, aqueducts, retaining walls, etc., how can these be rendered less hurtful to the refined feelings of the truly artistic engineer?

Before proceeding further, it might be well to say a few words concerning architecture, that is— "artistic construction, or graceful and decorated buildings." For a purely architectural work "grace embodied in structural contrivance and grace superadded" are necessary. It is obvious then that the work of the engineer should be equally with that of the architect, "the legitimate subject of graceful design, that is, art."

There should be no distinction between the engineer and the architect, save that arising from the convenience of a division of labor, the engineer confining himself to bridges, railroad constructions, etc., and the architect to buildings. We were careful in the foregoing to leave out of consideration all but the works of the *civil engineer*, for these only stand in close proximity to those of the architect. It is not necessary, nor is it desirable that there be steam engines in the different orders of architecture; but bridges and other such works can, and should be, for by attaching columns, entablatures, and other parts, we can render to the bridge, or any particular work of the engineer, any certain architectural style.

Let us now look to the opposition brought up against art in engineering: we have before us, the utilitarian, the empty pocket, and the art aristocrat. The utilitarian declares art is a luxury, and objectless; he has nothing in view save the immediate end of the work, and judges it accordingly. Now the reason for viewing the matter in this light is purely subjective, as necessarily the sense of understanding art is defective in the utilitarian. The harmonious working together of thoughts and feelings is necessary for a perfect comprehension of an object of art, which is only produced through the united action of hand, head, and heart. The utilitarian's view is certainly caused by the tendency of the times; a peculiar practical age are we enjoying, that is, we as a people have not about us that dreamy sentimentality of the theoretic German institutions, whence, it will be acknowledged, if art is to take a position in engineering, it must proceed.

It is true we see happy efforts to give to objects of handiwork an artistic appearance; we do well to imitate the common household articles of the ancients of a purely classical period. At present we are first technical, then, and only then, are we artistic; the age we say is a technical one; even in the fine arts, technical skill is more observed: we say of a painting, the effect of light or shade is good, the colors are well contrasted or blended, technical skill; so also in music, before we trouble ourselves with the depth of feeling or thought expressed. In this position are we at present, but are we to remain here? Are we not continually striving to rise higher in the scale of humanity? Are we not continually striving to widen the gap separating us from our Darwinian ancestor? The ape is a utilitarian, he builds or seeks himself protection from the raging storm, simply because of material necessity caused perhaps by some innate feeling. The first step in civilizatton is to satisfy our wants, and this in a most practical manner; this accomplished the mind seeks to improve itself, something higher is sought than simply to live, we wish to satisfy other than mere material necessities. Looking at many objects around us, from a utilitarian standpoint, how useless they appear. How senseless it seems to weight oneself down with trinkets. Fortunately, however, the refinement of civilization finds other expression than in requiring all objects to be absolutely useful. No utilitarian should have any sway in our state of civilization; he should be treated with contempt, or rather pity.

There is also an aristocracy of architects, who hold that art in engineering is out of place; this aristocracy maintain that a church is more than a palace, and thus better than a common dwelling-house, but the works of the engineer are placed by this class far below all these. We engineers should build the bridge so that his architectural highness should not wet his feet in crossing the river, that he undergoes no danger by a breakage, that the bridge be built therefore strong enough. We hold that there should be no degrees of beauty in buildings; a common Swiss cottage may be far more beautiful than a marble palace. It is not intended if art be applied to engineering, that a spiritual idea is to be expressed, even if there be manifold ideas connected with many works of the engineer. For example, if a bridge were to be represented over which Ceasar could have crossed the Rubicon, it would certainly have a different appearance than that on which Horatius kept at bay a whole army. No! the art aristocrat need have no fears of us encroaching on his domain, if he wishes to keep engineering and architecture as distinct branches.

Perhaps the chief opponent to art in engineering is the cost. First comes the fulfillment of object; then art is assigned a small place, if any; it comes late, much has been already expended on the former object, and but little is left for the latter. The cost can be effected by the strictest economy of parts of construction, and also by necessary parts and forms tending to ornament. In relation to the first: the strictest economy must admit of some freedom, as in the preparation of the material, in painting, the cost of yellow, red or green paint will be perhaps the same; the expense will not vary much if ashlar be hewn in square or oblong blocks. In building a bridge, much freedom is left the engineer, as to span, dimension of piers, etc., then why should not this freedom be devoted to an artistic choice, as luckily taste costs nothing. It is too material to allow of none but purely necessary parts to be brought into the structure; we should look to the effect of ornamentation in public works, which surely affect private dwellings. See the harmony in some of the older European towns, Nuremberg, Rouen, even affecting modern improvements. Why should we then not devote a little more of that all powerful agent, that is to say if possible, for "absque argento, omnia vana," to ornamenting, so that a good effect can have a result, not only on surrounding buildings, but also in the enlightenment of the people.

To devote a short space to art. What is art? We can say, it is caused by certain feelings in man which are expressed in some forms, and art in these is a perfect harmony between these feelings and the expressed form, which created by the artist should be understood by the observer. It is not necessary to our being that art is called forth, necessity does not call for art, the cry of the hungered is not for art, although peculiarly sensitive feelings are experienced. Common material necessity will not produce art; it is the feeling and understanding which causes its production, and only those possessing these can enjoy an object of art. Understanding without feeling cannot comprehend a work of art, neither can feeling alone; it is only the combined action of these that can give a just criticism on a work of art. For a comprehension of such there must be a corresponding idea in our mind, and a capability of judging, of comparing the object before us, and our idea; it is this which must be cultivated in the people, in order that if a work be really artistic it can be understood, thus raising man above the level of savagery.

The being of the art of building has its origin in merely natural necestities. Architecture is considered a fine art, and the fine arts call for spiritual investigation; how are we then to unite art with building so that an object of feeling and understanding be produced, at the same time all material, natural necessities being fully satisfied? We have nothing to answer from, but the limited space and the material employed. But is it at all possible to find anything spiritual in these? Yes! if both the space and material be in a manner idealized. Without going too deep into the discussion, we can say that certain spiritual relations can be regarded before the space be determined, the people for whom the work is constructed, the surrounding locality, etc. As to the idealization of material, of inorganic matter, there are certain laws which present themselves for consideration, such as those of gravity and strength, the destroying influence of time and weather, and the architect depending on these will produce a work approximating more closely to nature. By adhering to these laws, we must adopt certain forms and dimensions, certain properties of symmetry and harmony—these conditions the work must have in order to be judged artistic, and in such a degree that the observer can immediately see the arrangement according to nature.

The idealization of the object of building does not always produce a work of art; the tomb enclosing the remains of some aboriginal chief was built by his faithful subjects as a great high mound to show his greatness; the ethical determination of the work has in this case been idealized, but no object of art has been produced, any more than representing Charity as a boy untying a tin kettle from a dog's tail, even though the form of the boy be faultless, the dog perfection and the kettle marvellous in its representation. In the temple we have undoubtedly the first real object of art in architecture, wherein both object and construction have been idealized.

We see now what there is to be considered in this treatise, and will proceed, dividing the subject into the

following themes, which shall each be discussed in brief, viz.: The object of the work, the laws of strength and gravity, ornamentation, color, landscape, harmony, and style, of course all being applied to engineering.

The purely technical use of an object, if formed accordingly, will not render it beautiful, but should it not be conformable to the idea of construction the object becomes in a sense ugly. For instance, the technical use of a bridge requires that there be easy communication between both ends, that the river be not blocked; we can readily conceive the impression the work would make upon us were these requisites in any way disregarded. In engineering little is done to extend a work beyond merely material satisfaction, whereas in architecture a union of material necessity and certain ideas of art or beauty are almost inevitably observed. Why then should this not be the case in engineering? A common urn of to-day is a national necessity, so also were those of the Grecians 2,000 years ago—ours is a necessity, theirs, also, but with art.

We give our opinion expressive of the beauty of an object in nature, by certain impressions it makes upon us, by analogy to certain ideas of beauty in our minds: tenderness, sublimity, slenderness, or boldness, so also are we to judge of engineering works, to observe their conformity to nature. We can see now that the object and construction of the work are connected. Two drawings should be made, the first giving the technical design, the second, the same with certain immaterial changes and additions, which would render the work an object of real art. Great care should be taken that in ornamenting any work the limits be not overstepped, that the strict purpose be adhered to. How often do we see buildings which are absolutely ridiculous, or really hurt our feelings; imagine a warehouse in the form of a Grecian temple or a narrow foot-bridge built as a Roman aqueduct. In the garden of the Villa Palavicini, near Genoa, is a building the front of which is in heavy massive stone, the rear is light pretty Swiss cottage architecture. In these examples certain effects are produced, but little art.

In rendering a work pleasing monotony should be avoided, as in long lines of arches, which can be easily remedied. One of the greatest secrets of pleasing and proper architecture is correct proportion; how easily does the proportion of the height to breadth of a rectangular opening effect the most uninterested. Of this property of art, if we may call it such, we know no reason; the knowledge of correct proportion is inborn; there can be no other account given of it. Then we have symmetry, which in nature a law, should also in engineering be a law; we have symmetry of lines and of masses, the former requires exact symmetry on both sides of a dividing line, the latter only a symmetry of mass. By adhering to these laws impressions of dignity, clearness, and boldness result; if any spiritual idea be connected with a bridge it should certainly be clothed with these qualities. Of course, no rule without exception, even from the laws of symmetry there can be turnouts, without in any way disfiguring beauty; how picturesque are some of the Italian country palaces, with their combinations of high and low, wide and narrow parts, additions and extensions, how different all this to our modern dwelling house; perhaps this can not apply to engineering, but why not? If the necessary conditions allow a work to be unsymmetrical, positively nothing can be brought up in opposition. The relation between various parts of a structure should also be considered; in a trussed girder if its height be greater than the passing locomotive, the girder appears heavy, give it the opposite proportion, and it will certainly look lighter and more ornamental. Very little can be said concerning proper proportion which is ruled by laws, of which we know very little, but we ought to be ruled by good taste, which after all can alone produce elegant proportion.

In speaking of the object of the work, the relation in which the people stand to art, should be considered. There is not now that happy condition in which the ancients lived. No! the artist stood then as one of the people, the invention and production of a work of art went hand in hand, then was there no rank between the artist and artisan; then was there no critic save the people. At present we are in a different state, we are divided into the people and the artist, the former knowing but little of the doings of the latter. Happy are we to note that this state is being improved upon, the people are being awakened to a higher sphere of education rendering them somewhat more appreciative of real art; the time must and will come when we shall have higher thoughts than the mere fulfillment of material desires, the time must come when lectures on art will be delivered more universally to attentive students at our Polytechnic and other institutions of learning. The engineer should certainly make some allowance for the ignorance of the people in his artistic developments; what he builds is not for a selected few but for the community. The people should know the ornaments which are chosen; instead of the lotus and fig-leaf, why not the rose and ivy? the people know these and certainly greater asthetical effect would be produced by these, than by the representation of hot-house plants of which the people have no idea. If there are to be statues to adorn the bridge, choose known heroes, or men of note, not mythical or mythological figures. On the bridge at Heidelberg, Germany, is the statue of some prince, opposite to which is a Minerva; the people in their ignorance have christened her the prince's wife. What there is necessary is the proper cultivation, and having this the engineer need have no compunction as to the effect art will produce.

A theoretical study of the strength of materials will give to the engineer the proper form and dimension in construction, so that with the least possible material the greatest strength may be obtained. He cannot, however, carry out his calculations to the full letter; for instance, a beam requires theoretically to have the largest proportion of height to breadth at its middle point to diminish to naught at its ends. Not alone is the theory partially disregarded because of technical difficulty or impossibility, but also because of—art. The arch has generally a circular form, the one deviating mostly from the curve of the middle line of pressure; it is only æsthetical influence which causes this, as certainly the arch can be just as easily constructed in one form as another. We see in this the opposition between statics and æsthetics; which should have the supremacy? We answer neither: "the union of art of building with the laws of strength and gravity should be raised to an esthetical motive," in as much as an artistic inspiration introduces into laws (it matters not which) poetical impressions and deeper feelings; naturally such an ideal comprehension should not act as a destroyer of laws. The simple execution of statical laws causes a certain regularity of the whole work, but the mere fact that there will be no downfall of the structure does not call any very sensitive feelings into activity; however, if at the same time a certain life be given to the work, and we see a lightness and gracefulness about it, we say it is beautiful. The necessary technical laws are satisfied in simple construction, when there exists the required perfect equilibrium of all the forces acting; by art, the work receives, as it were, a coating or covering, which certainly will not effect its stability. In adorning a work strict regard should be paid to that part constructed on purely scientific bases, and the ornamentation should have a certain analogy, and in so doing a perfect harmony will be obtained, and neither the highly scientific engineer nor artful architect can feel slighted.

In ornamentation we have before us a field vastly extensive. It is a general impression that all those parts which do not strictly belong to the construction are simply ornamental; this idea is, however, erroneous, for who can tell where necessity ends and superfluity commences. In a very strict sense, all ornamentation is unnecessary,—a rough oblong block of stone will serve as a column as well, perhaps better, than the delicate Corinthian; but having advanced so far in culture and art, we say emphatically, the column must be rounded, it must have certain proportion of diameter of shaft to height, it must have capital and base—in short, it must be ornamental. We will not better the work by ornamentation any more than to render it more attractive; how cold and bare would the different parts in architecture appear denuded of all ornamentation, as in the framing of openings, and profiles of mouldings. To the artistic eye must this not be a glaring defect in Engineering? Decoration is not simply an annexed ornament but a completion of a work of art.

To describe suitable ornaments for various works in engineering we would have to pass beyond our province; but before taking up another topic we will offer a few suggestions, which might prove beneficial to ornamental engineering. As to quality, always a proper application and always the analogy are to be considered. The quantity should be regulated and care should be taken that the work be not too ornamental (sad sarcasm in engineering) as in the Gothic building on which every space is ornamented. As to the size of the ornaments are we also to pay attention; a small space with large ornaments is as false as a large space with small ornaments; this perhaps is all important, and a really artistic thought is requisite to render a work in any way perfect in this respect.

One of the first æsthetical impressions which each and every earthly object has upon us is its color; its effect is even more immediate than that of form; children, and even animals are affected by it, so that this topic, which although the least understood, requires the most thought. The educated mind will overlook many an imperfection, if the color be pleasing; monotonous scenery if illuminated appears grand. As above said, of all means of art, color, although so important and powerful are its effects, is the most difficult to comprehend; we can not define it, we can compare it, yes! as with temperature, a warm or cold tone, or with weight, a light or heavy shade. If the sense for color be the least active, it can be immediately seen whether colors harmonize, and in this fact lies nearly all that can be said on this subject. We dare not commence any physiological discussion on color. But to our subject: the color of the works of the engineer. What we should ever remember is the simple axiom, that color and form should agree in the artistic effect of a work. Color stands in about the same relation to building as ornamentation does, and should therefore be applied with similar restrictions. If different coloring is to be applied to a work, to give a heavy color to parts bearing heavy loads, and a light one to auxiliary parts, would be in a measure an artful reasoning for coloring. Color can be used to render a work lighter or heavier; a bridge may seem very pretty on a draughting board, but seen in reality, in perspective, it might appear heavy or clumsy; a covering of light paint might remedy this evil. There should be a perfect agreement between the effect of color on a work and its general charisteristics, hence the number of colors and the result of combination should be observed. Too many colors may destroy the impressions of repose, earnestness, and dignity belonging purely to works of engineering; perhaps pretty contrasting colors may be used with pleasing effect, for instance, on the railing of a bridge, as this has but little to do with the structure. Color is employed as a protective medium, as well as for decoration; naturally in practice these are combined. We can not, however, always use that color which would be artistically correct, the climate perhaps would be the first preventative, as above all, durability is required; the polychrome of the east remains long perfect after the simple coatings have been effaced by the weather in our land. In coloring a work it would be well to consider whether the material to be painted, or the coloring matter itself be more durable; in architecture this need not be discussed, but in engineering where works are subjected to the dampness of the earth, or in bridges, the vibrations caused by the passing trains; this is a point well worth the consideration.

We might tender some few suggestions which if observed might give to engineering more real art than it has hitherto been blessed with. Coatings of paint are proper where the building material requires it to increase its durability; the paint should not cover the original statical design, should not be applied so that the form be altered, but particularly no architectural part or form should be painted in imitation. Color has been employed to assist in finishing the form; a simple line of shadow might improve a moulding, but we can favor of no deception; this is too tricky and does not show a proper feeling for real art, we would not have

> "Rich windows, that give no light
> Nor 'ways' that block the 'road.'"

In considering the character of landscape, and its effect on works of engineering, we enter into conflict with nature and must needs tread carefully; if we study the different moments we will find some true harmony between the work and the landscape. Nature should be altered as little as possiale, the work should close on to the original form of the ground, open rock should be built upon, trees and water courses should be spared. How picturesque is a village built on a rocky mountain

side! The engineer thinks little of this, he has to remove the unevenness of the ground, etc., in fact to destroy nature. If you would render a bridge harmonious with surrounding scenery, the cost prevents, almost inevitably; take, for example, a light truss work or suspension bridge in some sublime Swiss landscape, where instead of this, one in massive stone with towering proportions would be the more proper. It is true that contrasts are also very pleasing, but then harmony is lacking.

Decoration often lends harmony to landscape, the impressions of rich or poor country, wild or mild, can be easily represented in the work. Proper choice of color can have good effect on this harmony; generally, contrasting colors are used, if the scenery be particularly green, a red tone can be given. What best harmonizes in every landscape is the old, grey, moss-covered stonework; this we must not allow to go too far, as the original idea might be lost and the work become a ruin.

The next and last, perhaps the most important question to be answered is, *In what style are we to build?* As regards periods and styles in architecture, we are now in a state of active fermentation; some maintain that only a few improvements are necessary to the already established relations; others wish for a new style with certain similarities to the ancient; still others who would do away with all existing styles, but can offer none in their place. We see now how impossible it is to answer the above question. Without any general culture as in the classical period, there can be no general style. It is the problem for the art critic to solve, he has to prove all and retain the best, and then he is to unite this sifted material with a certain spirit free from all mechanical ideas, with a spirit of pure feeling; with this something new can be developed. Let us hope that the new style will be "after the progressive idea, and not the archeological." No matter what it may be, Greek or Roman, a return to the mediæval art, or Romanesque, or a new Renaissance, whatever it may be, it will depend on the architect, whether it is to be "one in the right direction, a long-lived or a fleeting one." We cannot enter here into any discussion concerning what peculiar style can arise from such a combination; in all probability nothing absolutely new can be created; only from the now existing and known styles can a new one be evolved that is in an eclective combination of all. And so must this important question be laid aside; we would answer, build in the best if none can be created. Should we in our advancement ascend to such a state of pure art as was shown in ancient Greece would there then be no necessity of asking the question, in what style are we to build? It is true we might enter into a detailed description of the various existing styles and their applicability to engineering works, but we would then be overstepping our province, as it must be understood that the same reasoning is to be applied to engineering as to architecture.

With this we have come to the conclusion of our subject; it has been a general one, and very geuerally has it been treated. We could not however afford to enter more into detail; our idea was to show that notwithstanding prevailing impressions, that the works of the engineer should be made positively ugly, that they could and should be made positively pleasing, and be built in architectural and in an artistic manner. Not alone large structures as bridges of long span, but the less imposing, as it is in just such works that art is mostly indeed.

As referred to in the beginning of this paper we maintained that engineering and architecture were co-existant, then why are they not taught together? It is only then that we could expect to see real artistic engineering, and we would not need to sigh, that engineering so deserving of art is so devoid of it.

Los Angelos, Cal., *May, 1877.*

A BILL TO SECURE GREATER SAFETY FOR PUBLIC TRAVEL OVER BRIDGES.

Section 1. *Be it enacted by the General Assembly of the State of Ohio:* That all railroad bridges hereafter erected and designed or used for public travel, except those provided for in section seventeen of this act, shall be built to carry, for usual loads, not less than the following, in addition to their own weight, viz.: Bridges having a span of seven and a half feet, and under, nine thousand pounds per lineal foot for each track; those having a span of from seven and a half to ten feet, seven thousand and five hundred pounds per lineal foot for each track; those having a span from ten to twelve and a half ft., six thousand and seven hundred pounds per lineal foot for each track; those having a span from twelve and a half to fifteen feet, six thousand pounds per lineal foot for each track; those having a span from fifteen to twenty feet, five thousand pounds per lineal foot for each track; those having a span from twenty to thirty feet, four thousand and three hundred pounds per lineal foot for each track; those having a span from thirty to forty feet, three thousand and seven hundred pounds per lineal foot for each track; those having a span from forty to fifty feet, three thousand and three hundred pounds per lineal foot for each track; those having a span from fifty to seventy-five feet, thirty-two hundred poudns per lineal foot for each track; those having a span from seventy-five to one hundred feet, thirty-one hundred pounds per lineal foot for each track; those having a span from one hundred to one hundred and fifty feet, three thousand pounds per lineal foot for each track; those having a span from one hundred and fifty to two hundred feet, twenty-nine hundred pounds per lineal foot for each track; those having a span from two hundred to three hundred feet, twenty-eight hundred pounds per lineal foot for each track; those having a span from three hundred to four hundred feet, twenty-seven hundred pounds per lineal foot for each track, those having a span from four hundred to five hundred feet, twenty-five hundred pounds per lineal foot for each track; and in all bridge trusses of whatever length, the several members in each panel shall be so proportioned as to sustain, in addition to its share of the uniform load as above stated, such concentrated panel load as is herein provided for a bridge of a length equal to the length of the panel.

Sec. 2. Every railroad bridge shall be so constructed as to be capable of carrying on each track, in addition to its own weight, two locomotives coupled together, each weighing ninety-one thousand and two hundred pounds, on drivers, in a space of twelve and a half feet for each locomotive, and said locomotives to be followed by cars weighing twenty-two hundred and fifty pounds per lineal foot, covering the remainder of the span; and all railroad bridges shall be so projected that the loads above mentioned in section one, shall not strain any part of the material in such structure beyone one-fifth its ultimate strength.

Sec. 3. All bridges hereafter erected, and designed or used for public travel, on any highway or wagon road, shall be constructed to carry, besides their own weight, not less than the following standard loads, namely: City and suburban bridges, and those over large rivers, where great concentration of weight is possible, and on highways in manufacturing districts, spans of thirty feet and under, one hundred and ten pounds per square foot; spans from thirty to fifty feet, one hundred pounds per square foot; spans from fifty to seventy-five feet, ninety pounds per square foot; spans from seventy-five to one hundred feet, eighty pounds per square foot; spans from one hundred to two hundred feet, seventy-five pounds per square foot; spans from two hundred to four hundred feet, sixty-five pounds per square feet; on all other highway or road bridges, the standard load shall be not less than one hundred pounds per square foot, in spans of thirty feet and under; ninety pounds per square foot, in spans from thirty to fifty feet; eighty pounds per square foot, in spans from fifty to seventy-five feet; seventy-five pounds per square foot, in spans from seventy-five to one hundred feet; sixty pounds per square foot, in spans from one hundred to two hundred feet; fifty pounds per square foot, in spans from two hundred to four hundred feet. The floor-beam strength for each floor-beam for each wagon-way of city bridges, and those near large manufactories, shall be not less than thirteen thousand and five hundred pounds; for other bridges not less than eleven thousand two hundred and fifty pounds.

Sec. 4. In the construction of all bridges for public travel, either for railroads or common wagon ways, the stress on any material used in the construction of the bridge, in carrying the maximum load for which such bridge is designed, shall not exceed the following, namely: For the best quality of wrought-iron, in tension, long bars or rods, ten thousand pounds per square inch; for short lengths, eight thousand pounds per square inch, and against shearing force, seven thousand and five hundred pounds per square inch; and for the best quality of wrought-iron, in beams either square or cylindrical in section, in compression, the following, namely: Beams having a length of ten diameters, eight thousand one hundred pounds per square inch, with square ends, and seven thousand four hundred pounds with round ends; beams having a length of from ten to fifteen diameters, seven thousand eight hundred pounds per square inch, for square ends, and six thousand and five hundred pounds for round ends; beams from fifteen to twenty diameters, seven thousand four hundred pounds per square inch for square ends, and five thousand five hundred pounds for round ends; beams from twenty to twenty-five diameters, seven thousand pounds per square inch for square ends, and four thousand and five hundred pounds for round ends; beams from twenty-five to thirty diameters, six thousand and five hundred pounds per square inch for square ends, and three thousand eight hundred pounds for round ends; beams from thirty to thirty-five diameters, six thousand pounds per square inch for square ends, and three thousand two hundred pounds for round ends; beams from thirty-five to forty diameters, five thousand five hundred pounds per square inch for square ends, and two thousand and seven hundred pounds for round ends; beams from forty to fifty diameters, four thousand and six hundred pounds per square inch for square ends, and twenty hundred pounds for round ends; beams having a length from fifty to sixty diameters, three thousand eight hundred pounds per square inch for square ends, and one thousand four pounds for round ends; beams having a length from sixty to seventy diameters, three thousand two hundred pounds per square inch for square ends, and one thousand one hundred pounds for round ends; and for beams from seventy to eighty diameters, two thousand seven hundred pounds per square inch for square ends, and nine hundred pounds for round ends. If iron inferior to the best quality be used, either in tension or compression, the stress on the same shall be proportionately less than the foregoing standard for wrought iron of the best quality.

Sec. 5. Cast iron may be used in the construction of bridges, in compression only, and in lengths not exceeding twenty diameters, at the same stresses as those prescribed for wrought iron by this act, and in shapes other than square or cylindrical, whether wrought or cast iron be used, the stresses shall vary accordingly.

Sec. 6. Where wood is used in the construction of any such bridge, as aforesaid, the greatest allowable strains shall not exceed the following, namely: For oak in tension, twelve hundred pounds per square inch; for pine, one thousand pounds per square inch; and in compression, for oak beams of ten diameters, one thousand pounds per square inch; and for pine, nine hundred pounds per square inch; for oak beams from ten to twenty diameters, eight hundred pounds per square inch, and seven hundred pounds for pine; for oak beams from twenty to thirty diameters, six hundred pounds per square inch, and five hundred pounds for pine; and in oak beams of from thirty to forty diameters, four hundred pounds per square inch, and three hundred pounds for pine.

Sec. 7. It shall be the duty of all railroad companies or other corporations erecting a bridge for public travel, whether by contract or otherwise, to keep on the spot a competent engineer to superintend the work, who shall have power to reject any piece of material which may have been injured or which may be imperfect from any cause.

Sec. 8. All railroad bridges in this state used for public travel and having over a fifteen foot span, or having a truss, shall be inspected once every month by some competent person appointed by and in the employment of the corporation owning or using the bridge, for the purpose of seeing that all iron posts are in order, and all nuts screwed home, that there are no loose rivets, that iron rails are in line and without wide joints, that the abutments and piers are in good condition, that the track rails are smooth, and that all wooden parts of the structure are sound and in proper condition, and that the bridge is safe and sound in every respect. The person so inspecting railroad bridges, shall, as often as once in two months, make report, under oath, giving a detailed statement of the condition of each bridge to the general manager or superintendent of the rail-

road company employing him, who shall forthwith forward the same to the commissioner of railroads and telegraphs, and such inspection, in whole or in part, shall be made and reported as aforesaid oftener than once in two months, if required by said commissioner, and it shall be the duty of said commissioner to prescribe the form of blanks to be used by such inspectors of railroad bridges, embracing such information as said commissioner may desire.

SEC. 9. All highway bridges for public travel of more than twenty foot space, in or near any city, shall be carefully inspected as often as once in three months, and all other of such bridges having more than twenty foot span as often as once in six months, by some competent and suitable person. For city bridges, the mayor shall appoint the inspector, and the reports shall be made to him, and filed and preserved in his office for public inspection. For county bridges, the county commissioners shall appoint the inspector, and such reports shall be made to the commissioners and filed and preserved in the auditor's office for the use of the public. For all turnpike bridges, such inspection shall be made by an inspector appointed by the company using the bridge, and report shall be made to the county commissioners of the proper county, and filed and kept as reports on county bridges. All reports shall be made under oath, and the mayor or county commissioners, as the case may be, shall allow the inspector such sum for his services as may be just, which shall be paid in the same manner as claims against the city or county are paid.

SEC. 10. All corporations operating lines of railroad in this state shall, within sixty days from the taking effect of this act, report to the commissioner of railroads and telegraphs, to be preserved in his office, a detailed description of all bridges in this state of more than fifteen foot span, or having a truss, on their respective lines, and used for public travel. Said report shall be under oath, and made by some competent person in the employment of such company, and shall include the name of the stream or obstacle spanned, its location in miles from the nearest prominent point on the road, with the number or other designation of each bridge, the number and length of spans, their strength, the dimensions of all its important members, abutments, and piers, with the kind of material used in the same, and the foundation, and the age of the bridge, and the date when any important changes or repairs were made in the bridge.

SEC. 11. The governor shall, on the nomination of the commissioner of railroads and telegraphs, with the advice and consent of the senate, appoint some competent expert, at a salary not exceeding three thousand dollars a year, who shall have cognizance of the construction and maintenance of every bridge intended for public travel in this state, and who shall hold his office for the period of five years, unless sooner dismissed by order of the governor for reasons affecting his efficiency, in which case such reasons shall be given in writing by the governor, and shall be entered in full upon the public records in his office.

Such expert, before he shall enter upon the discharge of the duties of his office, shall pass a successful examination as to his mathematical and mechanical competency before a committee of three members of the American Society of Civil Engineers, and receive their endorsement in that behalf; and he shall, moreover, take and subscribe the following oath, to be administered by some officer authorized to administer oaths in this state, "I, ————, do solemnly swear that I am not directly or indirectly interested in any railroad or turnpike company, or any bridge company, or bridge patent, or in the manufacture or sale of any bridge materials, and that during my continuance in the office of inspector I will not become so interested, and that I will honestly and faithfully perform, with my best skill and ability, every duty in said office, without fear, favor, or affection, so help me God." Said oath shall be filed and recorded in the office of the governor.

SEC. 12. Said expert shall be subject to the direction of the commissioner of railroads and telegraphs, and all papers, calculations, reports, etc., pertaining to bridges, shall be filed and preserved in the office of said commissioner. It shall be the duty of said commissioner, whenever he is notified, or shall receive information, whether official or otherwise, or shall have reason to suspect that any railroad bridge, or any other important bridge is defective, to immediately cause the same to be inspected by said expert, and if found unsafe, he shall prohibit its use till put in safe condition and so pronounced by said expert.

SEC. 13. All railroad or turnpike officials having in charge the letting and construction of any bridge of more than fifteen foot span, or having a truss, and all county and state officials having in charge the letting or construction of any highway bridge or bridges of more than thirty-five foot span, shall submit to said expert a strain sheet and drawings of the proposed structure before work has commenced thereon, who shall examine and certify its correctness if correct, and make such alterations as may be necessary, if it be faulty in design, or scanty in materials, according to the standard prescribed in this act; and on the completion of such bridge, said expert shall critically examine the work in all its details, comparing and verifying the sections on the strain sheet with those of the actual structure, and if these last are unsufficient, to forbid the use of the work till the bridge is made sufficiently safe and strong. A copy of all plans and strain sheets submitted to said expert, shall be preserved in the office of the commission of railroads and telegraphs, and changes made from time to time, shall be noted on the records or files of said office.

SEC. 14. If said bridge, examined as mentioned in the last section, is up to the standard in all its parts, said expert shall give triplicate certificates to that effect: one to the builder, one to be filed in the office of the commissioners of railroads and telegraphs, and if a railroad bridge, the third certificate shall be given to the railroad company; if a highway bridge then a tablet shall be placed on a conspicuous part thereof, containing the third certificate, and also the names of the builders, the name of the officer or officers who accepted the work, the strength of the bridge as designed, and the year of its erection. Any person who shall willfully injure and fraudulently destroy such tablet shall be deemed guilty of a misdemeanor, and, on conviction thereof shall be imprisoned in the county jail not more than six nor less than three months.

SEC. 15. In all cases there may be an appeal from the decision of said expert to the commissioner of rail roads and telegraphs, who shall carefully enquire into the matter in dispute; and any modifications of the orders or decisions of said expert, or, changes ordered or made by said commissioner, shall be in writing, and spread upon the records in his office; and if said expert, from press of official business or other cause, shall require assistance, said commissioner may, from time to time, employ such assistance as he may deem proper, and pay for the same out of his contingent fund.

SEC. 16. It shall be the duty of the commissioner of railroads and telegraphs to stop the running of trains on all railroads in this state, where the company or companies operating the same either neglect or refuse to comply with the provisions of this act; and in case of injury to person or property, by reason of defect in any bridge in this state, this act shall not be construed or have the effect to diminish the liability of any corporation or authority, at the time of such injury, using the same. Any person willfully taking a false affidavit, under any of the provisions or requirements of this act, shall, on conviction thereof, be imprisoned in the penitentiary, at hard labor, not more than ten nor less than one year; and any person stealing, concealing or suppressing, or fraudulently destroying any paper, calculation, plan, or other thing, required to be kept in the office of the commissioner of railroads and telegraphs, shall, on conviction thereof, be imprisoned in the penitentiary, at hard labor, not more than three years nor less than one year.

SEC. 17. The standard loads on bridges of narrow gauge railways shall be thirty per cent. less than those provided in the preceding sections of this act. The word "bridge," in this act shall be held to include trestle work, each span of trestle being accounted as a separate bridge.

SEC. 18. This act shall take effect and be in force from and after the 10th day of May, 1877.

THE Louisville Bridge and Iron Company has the contract for three double track through wrought iron triangular truss spans, each 142 feet long, over White River, on line of Belt Railroad at Indianapolis, Ind.

ON THE MOUTHS OF THE DANUBE, AND THE IMPROVEMENT OF THE MOUTHS OF RIVERS IN NON-TIDAL SEAS.*

BY MAJOR STOKES, R. E.

The object of this paper is to bring before the officers of the corps the different methods that have been used for removing the bars of rivers discharging into non-tidal seas, with which the author has become acquainted whilst employed on a special duty.

He purposes first to treat of the general causes which lead to the formation of bars, and of the means to be employed for their removal.

Secondly, to mention generally the special treatment to which the bars of different rivers have been subjected.

Thirdly, to give a more detailed account of the works that have been successfully applied at the mouth of the Danube.

Round the mouths of most rivers are found shoals formed of the deposits of the river, and modified by the batter of the waves during rough weather; through these shoals the river forces a channel, which has greater or less depth, according to the state of the river and the sea. As this channel rises as a ridge between the deep waters of the river and the sea within and without it, and connects the higher shoals lying right and left of it, it resembles the neck connecting two hills in the same range; and though really a channel, is called the bar.

The height of the bar or depth of the channel, varies, as has just been said, under different conditions of the river and sea. When the flood waters of the river come down loaded with mud and sand they meet with a check at this ridge, but their impetus being greater than in ordinary times, the ridge itself is generally pushed farther out to sea, and the river waters being still further retarded by the opposing stationary mass into which they issue, the particles hitherto hurried along begin to fall to the bottom as the force of the current grows less and less, thus, on the new ridge, pushed out as above described, falls the coarse sand, making it grow up to larger dimensions than the original bar; further out will be the fine sand; and in the depths far out to sea will invariably be found mud and fine silt if the river flows through an alluvial soil. Should these flood waters be accompanied by a land wind, it is evident that the effect on the entry will be less injurious, the current being increased will carry the opposite ridge or bar farther out into deeper water, where the new ridge will require a larger base, and, consequently, take a longer time to grow; and the strength of the current will also carry the deposits further out to sea, and the shoals formed by them will be less dangerous to navigators.

If the floods occur at a time when gales are blowing into the mouth, the force of the current is checked, the bar is pushed out comparatively but a short distance, the deposits of the checked river are more immediately thrown down, and there is a greater danger of the formation of new and extensive shoals beyond and round the entry. After the subsidence of these floods the action of the waves generally drives the bar back to its original position after a struggle of weeks or months, according as the wind may prevail most from seaward or landward, and the fresh shoals are in the same manner driven in and piled upon the coast line, causing it to advance seaward. The case hitherto considered is that of a river issuing into the sea without littoral currents under different conditions of the wind; should, however, the sea have a constant current in one direction, a very important element is introduced, and the formation of shoals and growth of the bar may be brought under control.

As most rivers date from the remotest times, it is, of course, difficult to show their *first* effects, or to prove any theory of the formation of their bars; the author, however, calls attention to the following example which may tend to throw light upon the subject.

The river Vistula discharges into the Baltic by several branches, of which the western and most important formerly debouched into the Gulf of Dantzic, below the fortress of that name; the course of this branch was singular, it approached the coast in a direct line to the sea, to a point within 700 yards of it, when it took a sudden bend away from the coast and finally found its

* A Paper read at Chatham, England, October 16th, 1863.

way into the Gulf, at a point more than five miles further along the coast to the west. In the spring of 1840, however, the break up of the ice on the Vistula began from above, and immense blocks of ice were piled up in the bend above mentioned, until they formed a high dam which held back the flood waters of the river, and threw their weight upon a line of sand hills about 50 to 70 feet in height, which separated the river from the sea. Thirty-six hours of this pressure sufficed to the raging waters to break through this barrier, and ever since the western branch of the Vistula has debouched into the Baltic at this point; the channel which it broke through was, at first, 16 to 17 feet deep, but as the river current decreased, its deposits were thrown down and a bar formed so that only a channel of 6 to 7 feet remained.

The existence of bars may then be briefly resumed as due to two causes:—

1. The deposit of matter from the flood-waters of the river.

2. The effort of the sea to maintain the coast line by throwing up and packing together the sand and shells at its bottom.

The variety and amount of effect produced by these causes depend upon the action of the winds and currents, and on the changing force, duration, and direction, from which we may deduce the following axioms:—

1. That the mouth of every river has its own local peculiarities on which the successful treatment of it must depend.

2. That in studying to apply general principles to the improvement of any river, its local conditions must alone be allowed to guide such application.

That the fact of works having proved successful, or having failed at any river mouth, by no means ensures that the same kind of works will succeed at any other river mouth, unless the very same conditions exist.

We now proceed to consider the different remedies proposed for the removal of bars, or, more properly speaking, for the attainment of a deep navigable channel into rivers whose entrance are obstructed by bars.

These remedies may be briefly stated thus:—

1. By cutting a channel and maintaining it by dredging, assisted by the use of a rake towed over the channel.

2. By confining the river waters between piers which lead them across the bar and into deep water.

3. By cutting a canal to connect the sea with the river above its mouth, the river waters to be excluded from the canal to prevent its being silted up, the canal to lead into deep sea between piers, and kept clear by dredging.

The first of these methods may be practiced with advantage only where the channel to be dredged lies in a bay or gulf sheltered from the action of the waves. On an open coast, exposed to the swell produced by every breeze, a dredger cannot produce any perceptible effect. The least swell prevents her working, and for one day's perfect calm she will have two days of swell, even in summer, so that the work of one day is liable to be filled up the next; if, by the end of autumn, some little effect is produced, the long cessation of work during the winter months will certainly leave the waves at liberty to fill up the deepened channel.

A thorough trial was given to this system at the Sulina mouth of the Danube, in the summer of 1857, when three months constant dredging, relaxed only when there were too much swell on for work, gave no more than six inches additional depth, which was soon lost in the following months, although ther were then no floods to throw down deposit. The beating of the waves did the work, for the coast at Sulina is entirely exposed to all of the prevailing winds.

It is to be remarked that this dredging did not aim at the removal of the stuff in barges. In the narrow channel where the dredger worked there was not room for barges to lie alongside of her; even the dredger herself was frequently run into by vessels passing in and out. The stuff dredged was allowed to fall on a grating, and being thus broken up was carried away by the river current into which it fell.

At the canal entry to the Vistula, of which mention will be made further on, a dredger works successfully every day from May to October or November, but the ground on which she works is entirely protected from the prevailing winds.

In the channel at the mouth of the Oder, a dredger is also kept at work with good effect to prevent the growth of the sand bank by which it is sheltered while working.

Both at Sulina and off the Vistula the presence of the dredger has been found to be a great inconvenience to the navigation. At Sulina there was no advantage gained to counterbalance the annoyance and expense of the dredger; at the Dantzic canal entrance the maintainance of a channel 17 feet compensates the navigation for both.

Examples of the second method, namely, that of parallel piers, are to be found at the mouths of the Oder, Rhone, Danube, and Vistula. In the first and third instances they have been successfully applied, in the second and fourth unsuccessfully. The reasons for these various results will now be traced.

The Oder, not long before reaching the Baltic, passes through a lake called the Haff in which it deposits any of the matter that it may hold in suspensoin, and whence it continues its remaining short course to the sea in a clear and limpid stream. The bar, or rather the menacing sand bank at its mouth, is formed by the littoral current which attacks the line of high dunes extending westward for a distance of 12 miles, and brings in the sand which accumulates so fast to the west of the entrance, thereby necessitating the employment of a powerful dredger to keep this bank from growing inwards.

An examination of the charts of this mouth, which have kept for the last 120 years, shows that in 1739 there was only six to seven feet in the entry. From that time till 1776, efforts were made to render the banks at the mouth more solid, and to bring them closer together by groins of fascine work, which collected the sands travelling along the coast, and a survey of that year shows that this system had led to a considerable advance in the coast, and to but a slight improvement in the depth, which seems to have been its condition in the year 1816. At this time it was determined to have recourse to piers, and the works of that nature then commenced were steadily carried forward for nine years with an ever-increasing depth in the navigable channel, until in the year 1825, when the piers were completed, there was a channel of 17½ feet, which went on improving, till in 1845 we find a fair channel of 24 to 27 feet to the north-east, and a very broad channel of 18 feet to the north. It will be seen, however, that although this channel was cut through the old bar by the river current concentrated and directed by the piers, a part of that bar always remained in the shape of a sand bank running out beyond the west pier. It must be clearly understood that this bank, on which great stress has been laid by those who pretend that the piers have failed, is *not* a new formation; it's growth has, from time to time, tended to render the navigable entrance narrower, but, as has been observed above, it has ever been removed by the action of the current aided by dredging, so that in 1858, 33 years after the completion of the piers, the 18-ft. channel had always been maintained without any prolongation of them, and there was still a fair 24-ft. channel for steamers. It was then in contemplation to prolong the western pier in a direction converging on the eastern pier, so as to increase the scour, and check the travel of the sands along the coast from west to east.

It will now be useful to explain the causes of the bar forming at the mouth of the Oder, and of the great success of the piers.

The bar was formed, and the west pier sand bank is increased, by the travelling sand carried eastwards from the western head-land of the bay (into which the Oder discharges), by the littoral current. Some of the dunes attacked by the current are 200 feet high, and several of these big sand hills have been degraded at the rate of 12 feet a year. This littoral current circulates round the Baltic, from Denmark along the north coast of Prussia by Russia and Finland, returning down the coast of Sweden. It is urged forward by the prevailing westerly winds, but is at times held back by north-easterly gales, which, by banking up the waters, cause the sea-level to rise and the sea-water to pour into the haffs or lakes. When the gales abate and the prevailing winds and currents cause the sea-level to fall again suddenly, the waters of the Haff pour rapidly out through the Oder mouth, at the rate, generally, of some five miles an hour for some three or four days; this great scour, which recurs at not very long intervals, has served to maintain the channel, and to cut down the bank growing under the influence of the travelling sands. It is unaccompanied by any deposit on the bar, as the waters are quite clear, being, in fact, sea-water escaping back from the Haff. These peculiar conditions of the Oder mouth deprive the results gained by the piers of some of their value, as experience gained for the general question; but these results are, on the other hand, conclusive against the assertion that the works have failed of their object. The substitution of a channel 18 to 24 feet deep, maintained for 33 years, for one from 8 to 12 feet deep, must be allowed to be a success. The prolongation of the piers from time to time will, of course be necessary; but, if only required once in thirty years, the expense will be fully compensated by the results obtained.

At the mouth of the Rhone, piers have been projected, but the plan never advanced beyond the embankment of the river. It will be well to examine the causes that lead to the abandonment of the scheme.

The Rhone discharges through several mouths into the gulf of Lyons; the deepest natural outlet, and that by which the greatest body of water passes, is the easterly mouth. This mouth discharges in a direction exactly opposed to the prevailing winds, so that when the floods descend they find themselves immediately arrested, and the matter held in suspension is at once thrown down close to the mouth. At the same time, it must be observed, that the usual force of the current is very feeble, being less than a mile an hour, so that it has no chance of forcing a way through banks formed during the floods; and, on the other hand, the winter gales breaking directly on these banks pack and consolidate them, so that they advance, in their natural state, 40 to 50 yards a year. So feeble is the current, that the river, for 2½ miles above the point where it joins the sea, does not maintain the depth of 26 to 30 feet that it has higher up, and which here falls to 14 or 15 feet.

So much for the natural conditions of the river mouth, conditions the most adverse to the pier system. If one, however, considers the works that were executed there from 1852 to 1857, one can hardly admit that the pier system failed at the mouth of the Rhone; for piers in the sense understood, at the mouths of the Danube and Oder, were never carried out.

(*To be continued.*)

IMPROVEMENT OF THE SOUTH PASS OF THE MISSISSIPPI RIVER.*

OFFICE OF UNITED STATES LAKE SURVEY,
Detroit, Mich., April 5, 1877.

SIR: I have the honor to report the condition of the works carried on by J. B. Eads, for the improvement of the South Pass of the Mississippi River, on March 16, 1877. My last report gave their condition on November, 18, 1876.

REVERSE CURRENTS IN SOUTH PASS.

From time to time observations have been made to detect the existence of reverse salt-water currents underlying the fresh water in the South Pass, as such currents might have influence in maintaining a channel. It is well known that the tides in the Gulf of Mexico almost entirely disappear when the moon has zero declination, and reach their greatest values (about 1.5 feet mean rise and fall) when the moon has her maximum declination, either north or south. It would naturally be expected in a very low stage of the river that the high tides should send a considerable amount of salt water into the river; at times when there was no tide, less salt water would enter it, and at high stages of the river little or none. (Extreme low river reads —1.60 feet on the gauge at Carrollton, near New Orleans, and extreme high river reads + 15.70 feet. The specific gravity of fresh water being 1.000, that of sea water is 1.027.) Thus at South Pass light-house, on August 15, 1876, salt water was found on the bottom for the first time. Rise and fall of tide that day 1.72 feet, Carrollton gauge reading 7.60 feet.

On September 17, with a tide of 1.2 feet, salt water of

* From the Sixth Report upon the Improvement of the South Pass of the Mississippi River, by C. B. Comstock, Major of Engineers, Bvt. Brig. Gen. U. S. A.

specific gravity 1.010 was again found on the bottom, the Carrollton gauge reading 3.00 feet.

But on October 2, 1876, with only 0.3 foot rise and fall of tide, and Carrollton gauge reading 4.80 feet, brackishness at bottom was barely perceptible, the specific gravity being only 1.001.

On October 11, with a tidal rise and fall of 1.2 feet, the Carrollton gauge reading 5.35 feet, the specific gravity of water at bottom rose to 1.014 at nine hours before high tide.

On January 3, 1877, with a tide of 1.26 feet, the Carrollton gauge reading—0.60 foot, no reverse current was found three hours after low tide, but specific gravity at 28 feet depth was 1.013.

January 7, 1877, with tide of 1 foot and Carrollton gauge reading —0.80 foot at two hours before high water, there was a reverse current with a velocity of 0.7 foot per second at 15 feet below the surface, specific gravity 1.000 at surface, and 1.012 at 27 feet depth.

January 11, 1877, with a tidal rise and fall of 1.65 feet, the Carrollton gauge reading—1.00 foot at an hour before high water, there was a reverse current of 1.06 feet at 20 feet below the surface. Specific gravity at 27 feet was 1.012.

January 13, 1877, with a tide of 1.62 feet, Carrollton gauge reading —0.60 foot, there was, at four hours before high water, a reverse current with a velocity of 0.55 foot at 20 feet below the surface, the specific gravity being 1.006 at that depth.

January 15, 1877, with a tide of 1.65 feet rise and fall, the Carrollton gauge reading —0.30 foot, there was a reverse current of 0.71 foot at 20 feet below the surface.

January 19, 1877, with a tidal rise and fall of 0.75 feet, the Carrollton gauge reading —0.50 feet, there was a slight reverse current below 17 feet depth. Observation ten hours before high water.

January 26, 1877, with a tidal rise and fall during the day of 1.9 feet, the Carrollton gauge reading 1.40 feet, and the river rapidly rising, there was at two hours before high water, no salt water at any depth.

On January 7, 11, 13, and 15, the surface current was direct, and varied between 0.18 foot and 1.29 feet per second. It will be noticed that on January 11, 13, and 15, the velocities near the neutral plane changed very rapidly with changing depth. Possibly a part of this may be due to errors of observation. A Woltmann's wheel would probably have given more exact results if one had been available.

The data thus far given are all for the immediate vicinity of the South Pass light-house.

A few observations were made at the head of South Pass, near the lower end of Goat Island. Thus, on December 11, 1876, the water, at the depth of 35 feet, had a specific gravity of 1.016; Carrollton gauge read 0.75 foot.

January 24, 1877, at 35 feet depth, specific gravity was 1,008; Carrollton gauge, —0.30 foot.

From these observations it follows that at periods when the river stage is very low and the tides are the largest, there is, prior to high tides, a considerable upstream flow of sub-surface salt water past the South Pass light-house, the velocity of this flow sometimes exceeding a foot per second.

This salt water is found at the head of South Pass, and it doubtless extends far up the river in low stages. It would be of interest to ascend the river, when again low, to a point where the water is 100 feet in depth, and ascertain the amount of salt water there.

RECAPITULATION.

At the mouth of the South Pass, between November 18, 1876 and March 16, 1877, a few new wing-dams have been built, and some old ones repaired. About 16,000 cubic yards of material have been dredged out at points where the channel was worst. A storm of December 30, 1876, damaged the ends of the jetties and the wing-dams near them quite severely. 2,600 feet of the west jetty has been raised by mattresses 2 or 3 feet thick built in place; a layer of stone 0.8 foot thick on this portion gives it a height varying between 0.5 foot and 2.0 feet above average flood-tide. The outer end of this part is 700 feet from the sea end of the jetty; 167 new piles have been driven in the jetty.

Little work has been done on the east jetty.

The channel of 20 feet in depth at the mouth of South Pass, which on December 27, 1876, had a width of 200 feet from the Pass to the Gulf, has narrowed at a point near the sea end of the jetties so as to be but 70 feet in width, and at a point a little below the head of the west jetty, so as to be 180 feet in width.

At the head of the passes, the west T-head has been extended up-stream to meet the line of mattresses across the head of Southwest Pass, and its upper part has been made a solid dike. A line of mattresses has been carried from the east T-head down to the head of Goat Island. A solid mattress-dam (No. 6) has been built across the old east entrance to South Pass. About 30,000 cubic yards of dredging has been done, (making the total amount of dredging here 40,000 or 50,000 cubic yards). The river began to rise on January 24, and caused a sharp scour between the T-heads, so that 23.9 ft. could be taken from the Mississippi River into the South Pass on March 7, 1877.

Very respectfully, your obd't servant,

C. B. COMSTOCK,

Maj. of Engs. and Bvt. Brig. Gen. U. S. A.

The Hon. the SECRETARY OF WAR,

Washington, D. C.

STRENGTH OF BUILDINGS.

BY W. L. B. JENNEY, ARCHITECT.

The numerous accidents of late, both to public and to private buildings, naturally calls forth inquiry as to the cause of such disasters and the means of avoiding them in the future.

That they are unnecessary, no one for a moment doubts; but why are they so much more numerous than formerly? is a question of considerable interest at present, and which I think can be readily answered.

The accidents have happened to two classes of buildings—the one, large public edifices erected at great cost; the other, business warehouses. These two classes of accidents are due to very different causes and must be considered separately. Our new public buildings are built upon a much larger scale and are far more pretentious and costly than formerly and in consequence require more skill on the part of the designer and Superintendent. The day has past when a successful architect can grow up from an office-boy; he must now have a preliminary scientific training, and be as exact in his calculations of the different parts of an edifice as the engineer who designs a railroad bridge.

Every wall, pier, column, or beam in a building can be calculated, the maximum strains determined and such dimensions given to each detail of construction that the building shall not only be secure against accident, but shall be a homogeneous whole; that is, every part strong and no material wasted.

Such calculations to an engineer or architect accustomed to make them offer but few difficulties, and are sufficiently exact for all practical purposes; for, in order to avoid accidents from temporary overloading, defects in material or construction, a co-efficient of safety of from six to ten is introduced; that is the maximum load at any point shall not exceed one-sixth or one-tenth the crushing weight.

Unfortunately good designers and correct calculations are alone insufficient, for unless the work is properly erected, the building will be a failure and all the skill of the architect of no avail. Disaster may ensue and the architect be held criminally liable although he may have done his part equally well.

As an architect is generally superintendent of the execution of his own designs, the public quite naturally concludes that he has everything his own way, and is responsible for the workmanship of the several mechanics, the quality of the material, etc. This is true only within a very limited sense. The architect is the director of the work, but he is not paid to remain constantly at the building, to examine every bit of material that enters into the construction, and to see all work before it is covered up. This is the duty of a special employee, paid by the owners of the building, and known in England, where he is always employed on important constructions, as the "Clerk of the Works." He receives his instructions from the architect, explains the designs to the mechanics, and exercises a constant watchfulness over everything about the building. It is to be regretted that it is not the rule rather than the exception in the United States to employ a Clerk of the Works. It is the only way that the architect can know that his designs and specifications are being carried out in their true spirit and intent.

The second class of accidents, those to heavy wholesale warehouses, are usually due to another cause.

These buildings are erected as an investment, and, in consequence, must not cost more than a certain sum or it would be better to sell the ground or let it lie idle. But any increase in strength involves an increased amount of material, involving increased cost; therefore the tendency is to make the buildings light. If the architect does his duty by himself and his client, he will carefully calculate every part of the building, and notify the owner of the amount per square foot of floor that the building is calculated to safely carry—and this sum should be stated in the lease as the maximum load a tenant shall place in the building, and forcing upon said tenant all the responsibility of overloading.

Our city stores as usually built can be safely loaded with seventy pounds per square foot of floor, which being equivalent to the weight of a crowd of persons, is the lightest weight that any building should be calculated to carry, or otherwise a sudden rush from mere curiosity, or even an auction sale, might cover the floors with people and cause a frightful disaster. It would not be profitable to erect a building for a wholesale dry-goods store strong enough for a grocery or paper warehouse; and yet, if there are not some restrictions, a building sufficiently strong for the purposes for which it was designed may be greatly overloaded and disaster ensue. This is now the more likely to occur on account of the general use of steam or water elevators, which render all parts of a building equally accessible, and the upper stories, formerly used only for the lightest material, are more often stored with the heaviest goods, for in the busy season all our wholesale houses are liable to be short of room, and goods once on the elevator are taken to any story where there may be room for them.

It is well known that there are buildings in this city that have been overloaded, and dangerously so. Ignorance is the only cause for such recklessness, and the principle object of this paper is to call the attention of all interested in wholesale warehouses or buildings heavily loaded, to the fact that it is very easy to calculate exactly what is the safe load per square foot of floor, and as every dealer knows the weight of the goods he handles, it becomes a very simple problem to avoid overloading his building.

The business of our wholesale merchants is doubtless on the increase, and a busy season near at hand, and unless care and study is given to the question of loading buildings there will be a list of accidents involving loss of life and property.

Not many months since I was called upon to report the strength of a building used as a wholesale grocery. The building that could safely carry no more than seventy pounds per square foot of floor I found loaded with 200 pounds per square foot over considerable areas. Even during the few days that I was examining the building and making the calculations for strengthening it, marked changes took place that suggested the immediate necessity of blocking and jack-screws, and had not the tenant and owners acted with promptness a very severe accident would have occurred. And yet, as I was informed this building had been in use as a grocery warehouse for two years, and was at the time of examination loaded rather less heavily than usual.

Because a building has stood for a considerable period under excessive loads is no reason that it will continue to do so, for excessive loading weakens the construction and is a permanent injury.

We all remember not long since that the contents of a wholesale grocery on Randolph street was found one morning, floor, timbers, and all, in the basement. How long had the members of the firm and their employes run the risk of their lives every moment they were within the building? The same thing happened in New York only a few weeks since. We can scarcely expect that many cases of this kind will happen in the night; indeed, there is more reason that they should happen during the day, while the elevator is running and goods are being moved about, causing certain vibrations that materially increase the danger.

Tenants of loaded buildings must be watchful, especially if they are piling into them three times as much as they are intended to carry, and remember that it is the last straw that breaks the camel's back.—*Chicago Tribune.*

WE call the attention of our readers to the change in the address of the American Society of Civil Engineers, which will be until further notice 104 East 20th street, New York City. The following elections, changes and corrections in members' addresses are recorded for the month of April:

Additions:—James Dun, North Springfield, Mo.; Wheeler C. Durham, Civil Eng., Chicago, Ill.; Mordecai T. Endicott, Civil Eng. U. S. Navy, New London, Conn.; Bryant Godwin, Res. Eng., N. Y. State Canals, 551 Broadway, Albany, N. Y.; Arthur S. Hardy, Prof. Civ. Eng., Chandler Sci. Dept., Dartmouth College, Hanover, N. H.; George O. Knapp, Civil Eng., Hartford, Conn.; Nathan M. McDowell, City Eng., Allegheny City, Pa.

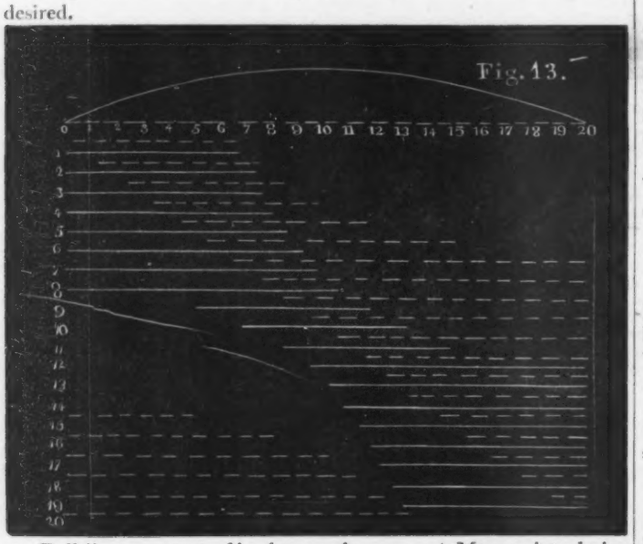
Changes and Corrections:—John Bogart, Sup'g Eng. Dept. Public Parks, 42 West 26th st., New York; Chas. O. Brown, Eng. Passaic Rolling Mill Co., 130 Chambers st., New York; William H. Burr, 50 Second st., Troy, N. Y.; Samuel H. Chittenden, East River, Conn.; Jacob M. Clark, Eng. C. R. R. of N. J., 119 Liberty st., New York; Richard D. Dodge, 58 Clark st., Brooklyn, N. Y.; Edmund L. Du Barry, 205 Hoffman st., Baltimore, Md.; James P. Gould, Eng. U. & D. and R. & C. R. R., Roundout, N. Y.; Alexander L. Holley, 56 Broadway, New York; Thomas Lafon, Newark (Knox Co.), Mo.; John McGee, Steubenville, O.; James Moore, Sup't C. R. R. of N. J., Elizabeth, N. J.; John Nader, City Eng., Madison, Wis.; Othniel F. Nichols, 112 Cambridge Place, Brooklyn, N. Y.; Stacy B. Opdyke, Jr., Ass't Eng. P. R. R., Lewiston, Pa.; Henry G. Prout, Lieut. Col. of 'Engs', Army of the Khedive, Vice Governor General of the Soudan, Egypt; Robert L. Read, Chief Eng., U. R. R., Transfer and Stock Y'd Co., Indianapolis, Ind.; Joseph Sewall, City Eng., St. Paul, Minn.; Herbert J. Shedd, 65 Westminster, st., Providence, R. I.; Edgar B. Van Winkle, "Rockingham," 56th st., and Broadway, New York; Charles D. Ward, 39 Hudson st., Jersey City, N. J.; David W. Wellman, Civil Eng., St. Paul, Minn.

ARCHES;

CONSIDERED GRAPHICALLY.

(*Continued from page 124.*)

while that from H depends on k and the inclination of the rib, it will not be easy to determine a general expression for the amount of load to produce the maximum stress in either flange. In working out any particular design it may be as well to determine the stress in each part of the flanges at first from a single load at a point of division, tabulate the stresses in place of bending moments, and add together those of like sign in order to obtain the maxima desired.



Full line = extent of load to produce max. + M on points designated.

Broken line = equals extent of load to produce max. + F between points designated.

Blank space for max. — M. do. do. for max. — F.

64. It may be useful to make a little numerical calculation on the rib of Fig. 11, 100 ft. span and 20 ft. rise, supposing it to be loaded with the four weights only which are shown in the figure. The maximum positive moment is plainly at 8. If the rib is made of a web and two flanges 2½ feet from centre to centre, what will be, with this load, the stress in each flange? If our figure were larger, we could scale the ordinate above 8 and get the bending moment directly, bnt, as the sketch is small we will refer to the table. We thus find that

$M = (.0815\times2+.1715\times4+.0019\times2-.0833\times3)\,50 = 34.31$ ft. tons.

Dividing by 2½ ft., the depth of the rib, we get 13.72 tons, compression on the upper flange and tension on the lower flange. As the middle ordinate is 20 feet, the one at 8 will be $20\times\frac{16}{25} = 12.8$ ft., or 7.2 ft. less than the crown ordinate; the tangent at this point will strike the middle ordinate therefore at 7.2 ft. above the crown, and its length will be equal to $\sqrt{30^2+14.4^2} = 33.28$ ft. Therefore the direct thrust along the rib will come from the proportion T : H :: 33.28 : 30, or, since H was previously found to be 7.175 tons, T = 7.96 tons, on both flanges or 3.98 tons on each. We have then, finally:— Compression, at the point above 8, on the upper flange, = 13.72 + 3.98 = 17.7 tons; Tension, on the lower flange, = 13.72 — 3.98 = 9.74 tons. With a good-sized diagram, these results can be easily obtained graphically.

The diagram for shear for this arch with the given load may be drawn for practice, according to the explanations lately given. Draw first the diagram as if for a beam, and then, laying off the value of V, at each end for this particular case, draw a line from the ends of V, through the middle of the span. Note where the shear changes sign.

65. Passing next to the parabolic arch, fixed at the ends, we recall from § 28 that, to locate the curve of equilibrium for a single load at any point, we need three ordinates, one at each end, and the third passing through the point of attachment of the weight, and that the three conditions by which these must be obtained are, 1st., that the change of span shall equal zero; 2d., that the total change of inclination shall equal zero; and 3d., that the total deflection shall equal zero. As expressed in the notation used, the three equations of condition are

$$\Sigma\, E\,F\,.\,D\,E = 0, \qquad (4.)$$

$$\Sigma\, E\,F = 0, \qquad (6.)$$

$$\Sigma\, E\,F\,.\,D\,B = 0. \qquad (7.)$$

Since it will not be easy to adjust the lines by trial so as to satisfy these values, we will proceed to derive expressions for the required ordinates.

66. Let I N L represent the desired curve of equilibrium for a weight W, attached to the rib A Q B, Fig. 14, at a point distant T G, = b, horizontally from the middle of the span. Let the span A B = $2c$, A I = y_1, G N = y_0 and B L = y_2. If y_1 or y_2 becomes negative, it is to be laid off below A B, but otherwise above. The figure represents y_2 as negative, and, in the majority of cases, y_1 and y_2 have opposite signs. If the rise of the arch = k, and A D = x, D E will, as before, § 45, = $\frac{k}{c^2}(2c-x)x$. A G = $c+b$; G B = $c-b$.

Taking up the first condition, we have

$$\Sigma EF\,.\,DE = \Sigma\,(DE-DF)\,DE = 0, \quad \text{or}$$

$$\Sigma\,DE^2 = \Sigma\,DF\,.\,DE\,. \qquad (9.)$$

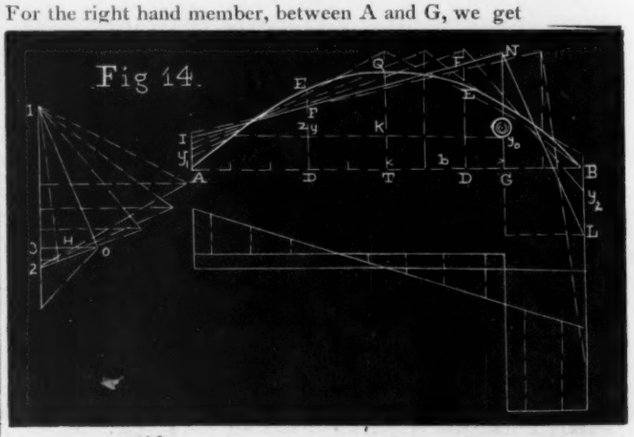
If a line be drawn horizontally from I, D F, as long as it is on the left of y_0, will be divided into a constant part y_1, and a remainder which varies with the distance from I. Therefore we see that

$$DF = y_1 + \frac{y_0-y_1}{c+b}x.$$

We get for the left hand member of (9.), when we introduce the sign of integration, exactly as in equation (10.), § 45,

$$\int_0^{2c}\frac{k^2}{c^4}(2cx-x^2)^2\,dx = \frac{16}{15}k^2c.$$

For the right hand member, between A and G, we get



$$\int_0^{c+b}\left(y_1+\frac{y_0-y_1}{c+b}x\right)\frac{k}{c^2}(2cx-x^2)\,dx =$$

$$\frac{k}{c^2}y_1\int_0^{c+b}(2cx-x^2)\,dx + \frac{k}{c^2}\cdot\frac{y_0-y_1}{c+b}\int_0^{c+b}(2cx^2-x^3)\,dx =$$

$$\frac{k}{c^2}y_1\left[c(c+b)^2-\tfrac{1}{3}(c+b)^3\right]+\frac{k}{c^2}(y_0-y_1)\left[\frac{2}{3}c(c+b)^2-\tfrac{1}{4}(c+b)^3\right]. \qquad [(e.)$$

For the portion between G and B, if we write $c-b$ for $c+b$, and reckon x from B to the left, we get

$$DF = y_2+\frac{y_0-y_2}{c-b}x,$$

the sign of y_2 being contained in the symbol. Then the integration for the right hand member of (9.), between B and G, or between the limits 0 and $c-b$, will give, when we substitute y_2 for y_1, and $c-b$ for $c+b$,

$$\frac{k}{c^2}y_2\left[c(c-b)^2-\tfrac{1}{3}(c-b)^3\right]+\frac{k}{c^2}(y_0-y_2)\left[\tfrac{2}{3}c(c-b)^2-\tfrac{1}{4}(c-b)^3\right]. \qquad [(f.)$$

The two portions (*e.*) and (*f.*) of the right hand member, being added together, when the coefficients of y_0, y_1, and y_2 are reduced, will be equated with the left hand member of (9.), giving

(*To be continued.*)

MOVABLE DAMS.

It is only quite recently that movable dams have been proposed in the United States, for the improvement of the Upper Ohio and the Kanawha Rivers, where it is desirable to make them deep enough to carry coal barges and rafts at low stages of water; and we think that few American engineers have a very clear idea of the details of such a construction and the methods of working. These dams have been introduced extensively upon French rivers, notably the Seine, the Yonne, the Marne, etc., as well as elsewhere, but as accounts of the structures built from time to time have been found heretofore only in the *Annales des Ponts et Chaussees*, they have not been accessible generally to inquirers in this country. It appears that, as long ago as 1818, Josiah White built a movable dam on the Lehigh river which was manœuvered solely by the pressure of the water; it consisted, we believe, of two gates; turning about horizontal axes at their lower ends, the upstream gate slanting down stream, resting upon and being supported by the lower one which inclined up stream. If the water between and below the two gates was permitted to escape, they revolved on their axes, falling one on the other, and leaving the passage open. This device is known as the "bear-trap." This dam was destroyed in the course of time and has well-nigh been forgotten.

For some fifty years various modes of constructing movable dams have been tried in the European rivers and many of the plans are very successful. Shutters turning about hinges at the bottom, wickets which revolve about horizontal axes a certain distance up, needles or bars removable by hand, caisson dams, etc., are to be found, some worked by hand, some by gears and chains, and some by hydraulic presses directly applied; in fact, the number of modifications reach some dozen or more. Perhaps the most accessible sources of information are the reports made to the Chief of Engineers, U. S. A., by General Weitzel and Col. Merrill, in the years 1874, 1875, and 1876, which give liberal extracts from foreign writers with plans and details. The report of the U. S. Commission to the Vienna Exhibition also contains an interesting account of two such dams.

Hagen, a prominent writer on hydraulics, in discussing the uses of movable dams and their importance, says:

"A complete solution of the problem seems to require that the pressure of the water, whether standing or flowing, should furnish the power by which the dam is erected or removed. Or, again, the construction must be such that, notwithstanding the requisite solidity of the structure, it can be managed with a slight power, for which only a few men and short time are required."

These dams are generally associated with locks to provide for the navigation up stream, and are sometimes intended to furnish a slack-water navigation of sufficient depth at low stages of the river. In this case the dam is only removed at times of comparative high water. But, in other cases, they are dropped to allow the passage of a number of barges, and closed again to cause the pond to fill. The barges then go rapidly forward on the artificial wave or *flash* which is created, and are thus carried in safety over what would be, otherwise, bars and shoals. One very curious circumstance is that the front of the wave, rolling over, as it were, travels faster than the remainder of the *flash*, so that the boats in advance can make a short stop at a landing below and still take the same wave again.

Hon. F. R. Brunot, of Pittsburgh, has devised a floating hydraulic gate which was recommended for trial in one of the dams of the Monongahela Navigation Company, and some description of this design may be found in the *Franklin Institute Journal*.

The construction of dams for the improvement of the Great Kanawha River is now in progress, although the deficiency in appropriations this year will retard the work. There are to be twelve dams in the 92 miles from its mouth at the Ohio River to Great Falls. In nine of them there will be passes, with movable wickets, opening a clear passage of 250 feet in length. Seven feet of water will be secured when they are closed, and the lift of most of the dams will also average seven feet. The three upper dams have a lift of 15 feet each and no movable portion.

As a type of the low lock and movable dam, we copy the description, given by the Chief of Engineers in the Report for 1876, of Dam No. 5, at Brownstown, some eight miles above Charleston, and now under construction.

"The lock, which is 364 feet in total length, 300 feet between hollow quoins, and 50 feet in clear width, is designed to pass at one lockage four coal-barges of the dimensions usual on the Ohio and Kanawha Rivers; that is, 130 feet long, 24 feet wide, and drawing 6 feet of water. It is placed in the river as near to its left bank as practicable, while giving a good exit and entrance for boats. The dam, about 560 feet long, crosses the river at right-angles to its direction, opposite the lower abutment, with a height from the rock of about 17 feet, and will raise the water nearly 11 feet above low water. The pass adjoins the lock, is 250 feet wide, and its floor is 50 feet long in the direction of the stream. The pier which separates the pass from the weir is 13.5 feet wide, 48 feet long, and 4 feet higher than the dam. The right bank of the river is protected by a masonry abutment, rising 10 feet above the dam, with wings extending to the top of the bank, above the reach of overflow.

"The lock walls will rest upon the rock, which at this point is between 3 and 4 feet lower than the mitre-sills. At the ends (the abutments for the gates) they will have a thickness of 16 feet, the interior faces will batter ¼ of an inch to the foot, the exterior faces will be vertical on the river side, while the back of the shore wall will batter 2 inches to the foot. Between the ends or abutments, the chamber walls are 12 feet thick at bottom of lock and 5 feet at top, the whole height being 20 feet; depth of water 7 feet, and lift of the lock 7 feet. The top of the lock is therefore 6 feet above the top of the dam.

"The upper and lower mitre-sills are placed on the same level, so that, by opening all the gates, the lock may serve as an extension of the pass. The mitre-sills are of stone, faced with timber; the floor of the lock is of concrete, covered with plank, except a space below each gate, which is paved with dressed stone. The angles, hollow quoins, mitre-sills, coping, etc., are of cut stone; the rest of the masonry will be of a much cheaper class, although not inferior in fitness, strength, or durability, all to be laid in the best manner in hydraulic cement. The chamber walls will be furnished with wings for the purpose of securing boats. The lock will be filled and emptied through valves in the gates, in addition to iron culvert pipes passing around the hollow quoins. It is proposed to build the gates of iron frames, covered with a sheathing of plank.

"In the lower abutment on the river-side is a well containing the gearing for tripping or throwing down the wickets of the navigation pass. This, as well as the chain-wells and gearing for operating the gates, is contained below the surface of the coping, and covered by iron plates; for, as the lock will be submerged in floods, it is necessary that no machinery or framing should be exposed on top of the walls.

"The floor of the pass is about three feet above the rock foundation. It is formed of concrete, supported front and rear by timbers framed into crib-work, the top is furnished with large timbers arranged to hold the journals, slides, etc., which are attached to them, and paved between the timbers with stone.

"The wicket is a wooden frame 13′ 5″ high and 3′ 8″ wide, covered with planks, and capable of revolving about an axis placed at the middle of its height. This axis is formed by the cross-head of an iron frame or *horse* which is itself movable about a horizontal axis fixed upon the floor. When a wicket is raised its foot rests against the sill of the floor, its horse is maintained vertical by an iron prop, the foot of which abuts against a *heurter*, an iron abutting piece fastened to the floor.

"The wickets, being placed side by side across the current, form, when raised, a dam to close the pass. A movable foot bridge is constructed up stream of the wickets, across the pass, to facilitate the operations of opening. To throw down or open a wicket, it is necessary to pull sidewise the foot of the prop, so that it shall slide across and clear of the front of the *heurter*. The prop, having lost its support, slides upon the floor down stream, the horse at the same time turns about its axis and falls upon the floor, the wicket follows them, and covers and protects the other pieces.

"If there is no water upon the floor, the wicket would be broken by the fall, but a very shallow cushion of water is sufficient in a great measure to destroy the shock. The foot of the *prop* is pulled away from the *heurter* by means of the tripping-bar, one end of which carries a rack gearing into a pinion in the well in the lock wall, worked by a crank on top.

"To raise the wickets, the lock-keeper stands upon the foot-bridge, and by means of a portable winch pulls up a chain attached to the foot of the wicket. The wicket rises, maintaining, however, a position nearly horizontal. It offers, therefore, but little resistance to the current. The *horse* and the *prop* follows its ascent until the foot of the latter, passing over the inclined plane which forms the top of the *heurter*, falls in front of it at the same time that the horse attains a vertical position. The axis of the wicket is now in its fixed position, and a slight push on the foot of it, or even the slacking of the chain, is enough to cause it to right itself and bear its foot against the sill."

In another column will be found some interesting remarks on the Tidal Waves which occasionally occur on our great Inland Lakes. We are now in possession of the confirmed report and many details of a similar disturbance of the waters of the Pacific Ocean on the coast of Peru and Bolivia, which took place on the 10th of May. The shock of an earthquake was first felt, when the ocean immediately upheaved, formed a wave some sixty feet high, and rushed shoreward with terrible velocity, destroying an immense amount of property, and, according to the reports, some 600 or 800 lives. Many of the villages and towns along the coast were completely overwhelmed.

One of the most prominent characteristics of the progress of civilization in the latter part of the nineteenth century is the rapid development of a taste for art in the masses, and the increasing demand for the production of such objects of art as the popular craving may require. While heretofore it has usually been the outside appearance of the house that has received the most attention, it speaks well for us that we are at last beginning to believe that the more beautiful we make the interior of our homes, the more sacred they become.

Demand necessitates supply, and the numerous art stores to be seen in all our large cities give unqualified evidence, not only of the bent, but the universal dominion, of this artistic craving of the age.

Among the many forms of art adaptable for house or garden decoration, and which has been brought within the means of the general public, is that class of statuary made from clay, or other material, or in the form of composition, foremost of which are the productions of John Rogers, of New York city. The peculiar eminence in this branch of art manufacture to which Mr. Rogers has attained, may be attributed as much to the truly artistic merit of the many works he produces, as to the excellence of the workmanship itself. There is always something lacking in the mere plaster cast of a work of art, a something which the sculptor's chisel seems alone capable of bestowing; yet in many of the beautiful groups of Rogers' statuary we have seen, we have been attracted towards them by the self-same spirit, doubtless, which inspired the artist when he designed them. Very true to nature in consequence of being very true to art, they form happy substitutes, in the place of such works as are entirely beyond the reach of any but the few, and present a means at a moderate cost, of decoration for indoor or out, which, when taste is displayed in their selection and disposition, gratify the senses and lend that charm to surroundings which culture at once requires and appreciates.

The catalogue embraces a large number of charming groups, as well as many pieces of less pretension and cost. The groups, as a rule, command attention by their artistic grouping, and the care with which the minutest detail is treated; the subjects generally are drawn from the historical incidents of late years, or from domestic sources, a variety which possesses the advantage not easily attained by a specialty, of affording ample scope to individual choice.

On those social occasions where custom has decided that some guarantee would be necessary in proof of regard, the most puzzling question is, what shall we give? A glance at Mr. Rogers' catalogue will, in most cases, determine an easy solution, and we think that in ordinary cases, not requiring special consideration, it will be found that nothing can be more appropriate than a group of his statuary, wherein will be found all that art requires in their production, spirit, truth and beauty, which, combined with the comparatively low cost, brings them within the reach of all.

We would advise all our readers to send for the Catalogue of John Rogers, 1155 Broadway, New York city.

ON THE MOUTHS OF THE DANUBE, AND THE IMPROVEMENT OF THE MOUTHS OF RIVERS IN NON-TIDAL SEAS.*

BY MAJOR STOKES, R. E.

(*Continued from page 138.*)

By the works executed, the engineers employed seem only to have sought to quicken the current whilst in the river; the works consists of dykes and causeways by which the outlets of six other branches have been closed and the river has been confined to one channel. Be-

*A Paper read at Chatham, England, October 16th, 1863.

yond the increase of power thus gained to the current, no step has been made towards removing the bar.

This method of proceeding has had the effect that might have been foreseen; the increased mass of river water has thrown an increased deposit; and the banks, instead of advancing at the rate of 40 to 50 yards a year, made in the year 1857 an advance of 300 yards forward.

In that year, the first after the complete embankment of the stream, the summer floods produced an increase of depth to 13½ feet, the former depth having been from 5 to 8 feet. This improvement lasted only four or five months, when the depth went gradually down to 7 feet. What the effect would be, of rapidly carrying out piers across the bar, as has been done at the Sulina mouth of the Danube, it is difficult to predict. The most violent winds blow directly into the mouth; and, for as much as 70 days out of 120, drive a heavy surf on to the bar. Still, the carrying of the river into the littoral current, which does cross the mouths from east to west, might have a beneficial effect. It is certain, however, that the Rhone offers but little chance of success to piers; it is also certain that they have never been really tried there. They cannot, therefore, be said to have failed at the mouth of the Rhone, though their failure *there* would constitute no argument against their employment elsewhere.

A project exists for entering the Rhone by a lateral canal from the Gulf of Foz, which, from its sheltered position, offers peculiar facilities for the execution of that class of work; the "Baie de Repos," into which the canal would debouch, being so calm at all times as not to interfere with dredging operations, and the bay itself having sufficient depth and a good bottom for anchorage.

The next example of the application of piers, which it is proposed to mention, is the Sulina mouth of the Danube; but, as the description of the works executed at this embouchure will form the subject of the concluding part of this paper, the author will here speak only of the results obtained by them, and of the general conditions of the locality which seem to him to have conduced to those results.

The Sulina is the least important of the three principle branches of the Danube, but it is that which has usually had the deepest navigable channel into the sea; its channel, from the point where it leaves the main river, 50 miles from the mouth, is the worst of the three branches, being everywhere narrow and in very many places encumbered by shoals which entail many delays and heavy expenses on vessels navigating from the principal ports of loading, namely, Galatz and Ibraila, whereas the other branches are broad and deep everywhere except at their mouths.

Without at this point referring to the circumstances which lead to the improvement of the Sulina mouth, it will suffice to say here, that the depth, on the Sulina bar before the improvements, was very variable, being sometimes as great as 12 feet, at others as low as 7½ feet; that the ordinary depth was from 9½ to 11 feet, and that it was more rarely about 10½ than below 9½ feet, and more frequently below 8½ than above 11 feet; that since the construction of piers the depth has never been less than 16 feet, and is usually 17 feet, there having been at times a good channel of 17½ feet.

The works commenced in April, 1858, were completed in August, 1861. The spring floods of that year had formed a menacing bank on the continuation of the south pier, and about 2,500 feet to seaward of it, but this bank was speedily broken down by the spring gales and carried away by the littoral current. In 1862, the floods threw down a similar bank, but without obstructing the navigation, and that bank was again removed by the action of storms, and currents. The supposition that a bar would form again outside the piers has not been in any way confirmed. The banks just mentioned have been the nearest approach to such a formation; but the rapidity with which they were removed seems to favor the supposition that the bar will only creep across the front of the piers when the general advance of the Delta shall have pushed the littoral current further away from them, and thus cause a double effect dangerous to the channel.

In the first place, the river current would then not be turned southward, and would throw down its deposits immediately in front of the piers instead of to to the south, as in 1861-62; and secondly, the banks thus formed, instead of being broken down by the gales and carried southwards, would be driven back on the channel, which they would still more choke. In the present year there have been no floods worthy of the name, and the current of the river has, consequently, been so feeble that the bank has formed between the heads of the piers, norrowing the entrance but not *barring* it. This bank is not disquieting, because being almost in the position of the old bar, and being distinctly traceable to the weakness of the current, there is not the slighest reason to doubt that the first strong flood will at once carry it away; the deep water being no farther off than in 1860, the littoral current is still there, so that the same causes for removing the bank existing, no one can doubt but that the same result will ensue. In fact, the entry at Sulina may be pronounced to be well in hand, for should any summer's survey show a decided advance of the coast line, it will always be in the power of the authorities charged to keep open the river, to extend the piers, and again reach the littoral current. No such prolongation seems at the present moment called for, and a comparison of this year's (1863) survey with that of 1857, shows that the 15 feet line is about where it then was, whilst the 18 feet line is now much nearer to the entry than in 1857.

There is then every reason to suppose that these works will continue to produce their effect for the time that they were originally intended to last, namely, for 5 or 6 years.

The fourth river alluded to as an example of the effect of piers, and the first that will be cited to throw light on the application of the canal system, is the Vistula, a river which indeed gives instruction on every kind of river works, whether in the channel or at the mouth.

Attempts were made to improve this river, as long ago as 1594, when rough piers were carried out, but it would seem without producing much effect, as the plan does not show more than 5½ feet. A subsequent map, bearing no date shows the piers of 1594 already absorbed in the advancing coast line.

The map of 1682, shows the Western Pier extended seaward and banks again forming behind it. A breach of the root of this pier through which the river cut itself a lateral communication with the gulf, 10 to 12 feet deep suggested the idea of obtaining a permanent channel independent of the mouth. The engineers of that day set to work to dredge the channel, throwing the stuff on the bank at the back of the pier, and thus aiding the natural deposit to form an island which became the right bank of a lateral canal leading from the river to the gulf.

The plan made in 1691, shows that this canal was then led into the gulf under a pier projected from this dredged island, and another of 1697, shows the canal shut off from the river by lock-gates, but shows, also, the difficulty of keeping open the canal, which was then only 7 ft. deep at one part and had a passage of 9 ft. only into the gulf.

In 1717, a further attempt was made to keep open the proper mouth by piers, which seems to have been abandoned, for a map shows that in 1724 a second pier was carried out at the entrance of the canal, the old pier prolonged, and the banks of the canal revetted; and as the canal itself was narrowed, its depth was doubtless increased, though no soundings are given.

In 1745 the Eastern Canal pier had been much extended into the gulf, but a depth of only 10 feet obtained. An extension of the pier at the mouth of the river had, at the same time, produced only 6 feet.

A subsequent map, records the apparent adandonment of all further attempt to open the mouth, and shows the successive prolongations of the canal piers, the western in 1775, 1796-97, 1802-03, the eastern in 1797, 1801, 1802, and 1802-5, which resulted in a depth of 13 feet in 1805.

A chart made in 1815, shows no extension of piers, but, as it gives no soundings, is of no value, except in showing the growth of buildings along the canal banks, and that the lock was solidly constructed in masonry.

The author was informed by the engineer who, in 1858, had charge of all the Prussian Harbor Works, that no efforts were available to keep open a greater depth than 10 feet into the canal before the year 1840. Each successive prolongation of the piers gave an additional depth up to 13 feet, but it was always immediately lost, and fell back to 10 feet. It was not till after the breaking through of another mouth several miles to the east, in 1840, as before mentioned, that the Prussian Engineers could congratulate themselves on having obtained a good entrance to the Port of Dantzic. As soon as that unlooked for, but fortunate, event took place, they commenced with praiseworthy activity to take advantage of a circumstance which had removed from the neighbourhood of the canal the continual deposit of sand which choked it. The river was at once shut off from its old course, by a dam through which vessels of small tonnage and rafts pass by means of lock-gates, on the sill of which there is a depth of 8 ft. The old mouth was cut off from the sea by a solid dam built across its channel; the old lock-gates, at the entrance to the lateral canal were removed, being no longer necessary, and the piers at the mouth of the canal were greatly extended.

By these means an excellent channel of 17 feet was obtained, and has since been maintained by constant dredging at the head of the east pier.

As already mentioned, the dredging is carried on under peculiarly favorable circumstances, as the Gulf of Dantzic is land-locked, and gives no rule for what could be done in the open sea.

The author has adduced the case of the Vistula as his last example of the effects of piers, and his first of the application of the canal system; but it is now time to examine why and how piers have failed—and how, if at all. the canal can be said to have succeded.

In the Gulf of Dantzic there can hardly be said to exist a littoral current. The littoral current of the Baltic, from west to east, passes along the Helas—the long low natural breakwater forming the Gulf of Dantzic—and strikes against the coast which then immediately tends to the north; the main force of the current is then carried northward, but a portion of it sets into the Gulf of Dantzic, from east to west from the point of contact, whilst a second current passing round the head of the Helas sweeps along the shore of the gulf, and traveling from west to east, meets the main current somewhere opposite the old mouth.

No more unfavourable circumstance for the opening of the river could be imagined.

The river issuing into slack water at the meeting of two currents threw down its deposits at once. The easterly current being, if anything, the stronger, these desposits were slightly carried to the west, just sufficiently to fill up the canal entrance. One cannot be surprised, therefore, at the failure of the Vistula piers.

As to the canal, it is not an example of the cutting a channel through a delta such as has been done at the mouth of the Ebro, and has been proposed for the Danube; a better channel having, by an accident, made its appearance behind one of the piers, advantage was taken of it, and an island formed outside of it.

Nevertheless, adroitly as this was done, persevering as were the efforts of the Dantzigers, for more than 150 years, to keep this channel open to sea-going vessels, it was not till the event of 1840, which removed the mouth so many miles to the eastward, that anything like success was obtained, and then only by employment of piers and by dredging.

Who shall say then, decidedly, that one system has failed and the other succeeded? Rather let it be said that engineers, taking advantage of nature's help, have used one system and the other, each in its measure, according as local circumstances directed, and that any attempt to lay down any one system, dogmatically, without reference to the locality, would assuredly fail.

The only instance in Europe of a river opened into a tideless sea, by means of a lateral canal, is the Ebro in Spain; but, here again, the experience gained does not allow the author to say that a decided success has been achieved, nor does the example bear on the general question, for the canal opened is so small that it will not admit sea-going vessels; and although nominally completed in the autumn of 1861, it had not been opened to general navigation in March, 1863.

This canal connects the Ebro with the Port of Alfaques, a small gulf formed by the delta of the Ebro to the south of the embouchure.

The length of the canal is 10,734 metres, its depth 2.70 metres, and its width 10 metres.

It leaves the Ebro at Amposta and passes through

two locks before arriving at the sea; at the first of these there is a fall of 1.50 metres, and at the second, which is in the Port of San Carlos, there is a fall of 2.20 metres. The canal is nourished by a smaller one, led out at Cherta, 29 kilometres above Amposta. This second canal also irrigates the Delta of the Ebro; its level, in the basin of Amposta, is 4 metres above the sea canal.

Ample means thus exist for flushing the channel and keeping the locks clear of deposit, which, nevertheless, forms to a considerable extent.

The sea entrance is led into the Gulf by dykes which direct the flushing, and thus increases its effect. From what has just been stated, it will be evident that this kind of canal would be applicable only where there is so rapid a fall in the river near its outfall as to give the required head of water within a reasonable distance. On the Danube, for instance, even if the canal would admit vessels frequenting that river, which it would not, no means exist for forming an alimentary canal furnishing the means of flushing.

When the river is low, and that generally happens when the navigation is most active, there is a difference of barely 3 feet in the level on a length of 50 miles; and the ground to be traversed by an alimentary canal is a swampy marsh intersected by lakes, through which a canal only could be led at a great expense. Again, then, let it be said, that local conditions must decide the choice of works; and though a canal, of dimensions sufficient for river craft, and fed by a canal at a high level, may have been opened on the Ebro, it affords no argument in favor of a similar work elsewhere, where the same conditions do not exist.

There can be no empiric cure for river bars; the remedy for the evil must be sought by patient study and examination of the locality where it exists, and founded on a consideration of all the disturbing causes, winds, currents, and quality of water, so different on different coasts and even at different points of the same coast.

Having now considered generally the causes that lead to the formation of bars across the mouths of rivers discharging their waters into tideless seas, and the systems of improvement that have been applied to certain rivers in Europe, the author will next proceed to give a detailed account of the works which have been carried out at the Sulina mouth of the Danube. It will, however, be necessary first to give a short sketch of the considerations other than technical, which are involved in the improvement of this river, which alone will account for works having been carried out in that branch of it which has been generally admitted to be the least suitable for navigation, and for the temporary character of those works.

Prior to the year 1829 the mouths of the Danube were held by the Turks, and it is said that under their direction every vessel leaving the river was obliged to tow a heavy rake to sea over the bar, so as to raise the sand, and let it be carried by the current away from the channel. It is even said that, in consequence of this treatment, there used to be a depth of 14 feet on the bar. These assertions are not worthy of much belief; no written record is in existence establishing their accuracy, and a strong reason exists for disbelieving them, which will be presently mentioned.

From 1829 till 1854 the Russians had possession of the Delta of the Danube, and in 1840, the navigable channel having become very shallow, the Austrian Government called upon Russia to take steps for improving it. A convention was signed, by which Russia engaged to keep a steam dredger employed in removing the sand which had encumbered the channel. This dredger worked but at rare intervals, and constant complaints were made against Russia for not keeping open the channel, which went so far as to accuse her of not only not trying to remove the obstacles, but of adding to them by sinking vessels in the channel. It was at this time that the condition of the river under the Turks was held up in contrast to its state under the Russians, and the power of the rake was so much insisted upon.

After the Crimean War, the free navigation of the Danube having formed one of the principle preliminaries of peace, a special arrangement for its proper administration was stipulated for in the Treaty of Paris, and the improvement of the mouths of the river was confided to a Commission, in which the Seven Powers who signed the treaty were represented, each by a delegate.

This commission, of which the author of this paper is the British member, entered upon its duties in November, 1856, and has ever since remained in office. Its principle duties were to free the mouths of the Danube from the obstacles that hindered their navigation. It may be mentioned here, that before the Russian occupation of the Danube, in 1829, the trade of that river was very insignificant. By the treaty of Adrianople, the Russians secured to the principalities a right which they had accorded to them during their occupation, of freely exporting their grain, which was previously a Turkish monopoly.

From this time the Danube trade went on gradually increasing, until the abolition of the English Corn Laws gave it a great impulse, as shown by the exports of 1847, which bounded up to more than 1,800,000 quarters from 1,200,000 quarters in 1846, and from 230,000 quarters only in 1837. Since 1847 the trade has steadily increased, excepting in the years affected by the Hungarian Rebellion and the Russian War.

One of the first cares of the Danube Commission was to seek for means of temporary improvement, whilst a proper study of the river was being made to ensure the proper application of permanent works. In the spring and summer of 1857, a full trial was given to the dredging and raking systems during a strong current, when, if ever, they should be successful.

A heavy iron harrow was towed over the bar from 50 to 80 times a day for two months, on as many days as the weather, which was generally fine, permitted; at the same time, a powerful steam dredger was at work in the channel, but their united efforts did not do more than increase the depth by about 6 inches, and when the flood current became weak even this much was lost, and the raking and dredging discontinued.

The rake only scratches up the bottom, but does not raise the mud and sand into the current. Near the bottom the current is feeble, and sometimes even running inwards, if, then, a rake passing 50 to 80 times in a day produced no effect, how could the vessels going to sea, which before 1829 did not number as many per month, deepen the channel 4 or 5 feet? One practical question, moreover, has never been answered, how did the rake get back again? For there were no tugs in those days, and the rake was too heavy for a boat to take on board or tow back. The intermittent working of a dredger in the open sea may be also set aside as unequal to the task of deepening a channel over a bar exposed to all the prevailing winds, for the channel dredged to-day is filled up by the swell of to-morrow, as the experience of 1857, at the mouth of the Sulina fully proved. In the course of 1857, surveys of the different branches of the Danube, forming its Delta, were made, and reports received by the commission from their own engineer, Mr. Hartley, an English civil engineer, and an engineer sent by the Russian Government, to aid their commissioner.

(To be continued.)

WATER SUPPLY FOR NEW ORLEANS.

REPORT OF CITY SURVEYOR.

SURVEYOR'S OFFICE, NEW ORLEANS, *November 14, 1876.*

To the Hon. Mayor and Administrators of the City of New Orleans:

GENTLEMEN.—I have examined and carefully considered the question of a full and permanent supply of suitable water for the City of New Orleans, and now have the honor to report the result of my investigations, and to transmit, herewith, for your information certain drawings and approximate estimates, etc., relating to the same.

There is no city in the Union of the size and importance of New Orleans where such an inefficient system exists, and perhaps none where the natural advantages are greater for having at all times and for all purposes, an abundant supply of the very best and purest water that could be desired.

The recent severe drought here of over two months' duration, and the inconveniences consequent upon the depletion of nearly all cisterns, together with the inefficiency of the present works, and the dangers imminent thereby from destructive fires, has directed public attention anew to the necessity of having a more reliable system of water supply, and furthermore, to have the subject at once agitated with a view of bringing about such a desirable result at the earliest practicable moment, consistent with the financial interests of the city.

There are two attainable sources from which New Orleans can be amply supplied, *viz.*: either by means of the Mississippi or the Tangipahoa rivers, and the object of this investigation has been to gather and submit for your consideration certain items regarding the relative advantages and disadvantages of each, so that the plan promising the greatest amount of good, may be entertained as the proper one for adoption.

The Mississippi river has the advantage of being in close proximity to the point of consumption, while the Tangipahoa has the disadvantage of being many miles distant. The Mississippi, on the contrary, has the disadvantage of being in a low basin and of a muddy nature, and will have to be clarified by means of costly structures before being rendered acceptable for use, and afterwards lifted at great and constant expense by powerful machinery; while the Tangipahoa has the advantage of being beautifully clear, and can be tapped at such an elevation that the water will flow of its own accord, and thus acquire no extra machinery or expense for raising it to the highest level established for consumption. The Mississippi would possess one considerable advantage in the use of forcing engines, and the facilities afforded thereby through a slight increase of power without much additional expense, in furnishing water to higher elevations at any time in the future when such an improvement may be required; whereas the Tangipahoa with a fixed source or head must remain always with a fixed capacity in that respect, and without any opportunity of increasing its force or power, except by great changes and much larger outlays. A considerable though remote disadvantage would exist in the long line of piping from the Tangipahoa, which would be subject to interruptions during invasions of an enemy, thus cutting off temporarily a supply of water; whereas, by the use of the Mississippi, all of the works would be concentrated within the limits of the city, and thus any such dangers would be obviated. The supply from the Mississippi would be almost unlimited, while that from the Tangipahoa, although comparatively limited, would yet be sufficient, without exhausting its full low water volume, to furnish abundantly a population of more than tenfold that which the city contains at present.

With the use of the Mississippi, it would be necessary not only to enlarge and remodel the entire old works at or near their present location, but also to construct at two other suitable points in the Third and Sixth Districts another set of new works similar in general design, so as to ensure an adequate supply of water for the entire City. This distribution from three separate locations would become expedient on account of the peculiar conformation of the inhabited portion of the City, in the disproportion of its width to its length, and the greater difficulties which would exist for supplying its elongated front of twelve miles, from the one point now established.

The improvement of the old works, and the construction of the new ones, should conform to a general plan, having for its object the furnishing of clear or settled water freely, to the same elevation as that which could be obtained from the Tangipahoa river, or at least to the third stories of all buildings within the city limits.

To accomplish these results, it will become necessary in the first place to provide for the construction of a requisite number of settling reservoirs. The Mississippi water in its natural state is too muddy for domestic uses, but after remaining in a condition of rest for several days, and the alluvial matter held in suspension is allowed to subside by certain appliances, it is susceptible of becoming as clear and wholesome as the inhabitants of any city could desire.

These settling reservoirs should be built in the ground by means of excavations as near the river bank as practicable, and to a depth of about fifteen feet below the natural surface. This would make the bottoms of the reservoirs about on a level with the surface water in the river at its lowest stage. The advantages of such an arrangement would be manifest in the facilities afforded for assisting in the filling of the reservoirs through self supplying pipes connecting with the river, during a large proportion of the year, when the surface of the water is at any of the points above its minimum or low-

est level. Whenever the water, however, is at any of the stages below that of flood height, the deficiency in filling the reservoirs through the pipes must be provided for by the agency of steam power, and to this end one or two pumping engines of light capacity will have to be located adjacent to the line of front compartments for that purpose. As the lowest stage of water in the river continues but a very short time in the year, it is evident that the maximum working power of these engines will only be called into requisition at long intervals and the expenses, therefore, of operating the machinery will be reduced to an average of what would be required between the extremes of high and low water or to about one-half of that which would be incurred by constant use.

After the water is clarified and becomes ready for use, it is intended that the pumping machinery shall take it from certain rear compartments at these reservoirs and force a supply directly to the main underground pipes as well as through them to a certain number of stand pipes, or small vertical reservoirs, so located and distributed throughout the city that they would answer the same purposes, at comparatively little cost, as one set of large elevated distributing reservoirs concentrated at each of the three points selected. On account of the flat surface, or plateau upon which New Orleans is situated, and the absence, therefore, of any suitable natural elevations, it becomes a question of enormous expenditure to construct reservoirs to a proper height for distributing purposes, as compared to the plan above suggested for receiving reservoirs on a lower level near the river bank. The same power which would be consumed in lifting the muddy water from the river to these elevated reservoirs, there to become settled, would suffice to supply the clarified water, with the aid of the stand pipes, directly to all the points of consumption. It is plain, therefore, that by this arrangement the expensive elevated reservoirs could be dispensed with, and a great saving or reduction thereby will be made in the total outlay for accomplishing the ends desired.

The construction of these reservoirs after the manner and plan proposed, is deemed the best and most economical that could be adopted to secure the benefits contemplated. The principal object to be obtained being the supply of clear or settled water, it is of the first importance to have the required quantities pass through the process of settling *before* it is touched by the main pumping engines, and certainly the cheapest mode of accomplishing this is through the construction of suitable basins for holding a sufficiency of water as near as possible to the natural surface, adjacent to the river bank or source of supply.

New Orleans is peculiarly fortunate in her topographical situation as compared with other large cities in the Mississippi Valley, for carrying out the conditions prescribed for a successful supply of river water. In the first place, all her buildings, or the third stories of the same are practically on the same plane above the standard low water level of the river, which would necessitate merely a minimum force of steam power to supply all buildings alike, and secondly, the river bank bears such a favorable relation to the river itself, on account of the slight differences between the extremes of rise and fall, that the cost of constructing and supplying the receiving reservoirs as designed, would also be reduced to a minimum figure. At St. Louis, Cincinnati, Louisville, Memphis and Vicksburg, owing to the elevated and uneven nature of the ground, a great disparity exists between the highest and lowest building sites, and this condition, taken in connection with the greater rise and fall in the river at those places, must necessarily cause a much larger outlay and expense in providing for and delivering the water to these additional and irregular heights.

There are difficulties not to be overlooked and which must be provided for, in the removal of the sedimentary deposits which would be from time to time collecting in these settling reservoirs. The accumulations cannot be completely disposed of by being washed back into the river, on account of the bottoms of the reservoirs being located too low to admit of this expedient, and the difficulties, therefore, must be dealt with in some other practical manner.

It is proposed to have suitable derrick arrangements to be attached to the several settling compartments and by some ingenious contrivance, the sedimentary matter can be scooped up and lifted the short distance to the surface, and thus easily deposited in carts to be hauled away. This material would be exceedingly valuable to the city for many years to come in filling up the many ugly holes over the river front, especially in the First District, and afterwards to property owners for filling up and raising low lots, thus utilizing that which might otherwise become a waste. In this way it is calculated that the removal of these sedimentary deposits, at stated intervals when required, would cause little or no expense to the city or upon those having control of the works.

In carrying out the plans herein proposed, there would be no actual necessity for using the old elevated reservoirs; but as they exist and cannot be put to any other beneficial use, it may be proper to maintain what is left of them in order to hold a surplus of water for fire purposes and as a substitute for one stand pipe for the District in which they are located.

It is calculated that the water works at their old location when remodeled and improved, would supply the city for all purposes between Canal street and Napoleon avenue. The other or new works to be located at some suitable points in the Third and Sixth Districts, should be duplicates as to machinery, reservoirs, etc., of the improved old ones, and these would supply respectively those portions of the city between Canal street and the Barracks, and between Napoleon avenue and the upper limits of Carrollton. The economy and advisability of this arrangement or distribution of the works, would consist principally in overcoming the difficulty of constructing all the reservoirs together of the total capacity required at one single point, on account of the large and valuable space to be occupied in the center or heart of the city; and, moreover, in the advantages to flow from having three separate and distinct sets of pumping engines so that in case of accident and delays to one, the others would measurably supply the deficiency and cause comparatively but slight interruptions in the delivery always of the maximum quantity of water.

The approximate estimate for cost of the improvements as above contemplated would be as follows, *viz.*

Constructing settling res'vrs at or near old site	$300,000
Light pumping engines for supplying same....	30,000
Additions and improvements to present large engines.....	15,000
Two stand pipes or vertical reservoirs.....	50,000
Expropriation of property required.....	20,000
Total for remodeling and enlarging old works.	$415,000
Constructing settling reservoirs in Third District.....	$300,000
Light pumping engines for supplying same...	30,000
Forcing or heavy pumping engines, machinery, etc.....	175,000
Three stand pipes or vertical reservoirs.....	75,000
Expropriation of property required.....	20,000
Total for new works in Third Dristrict.....	$600,000
Constructing settling reservoirs in Sixth District.....	$300,000
Light pumping engines for supplying same...	30,000
Forcing or heavy pumping engines, machinery, etc.....	175,000
Three stand pipes or vertical reservoirs.....	75,000
Expropriation of property required.....	10,000
Total for new works in Sixth District.....	$590,000

To these figures must be added $500,000 for the estimated cost of improving the old and laying additional pipes to accommodate the whole of the present inhabited portions of the city.

Total estimated cost of supplying the entire city of New Orleans with clarified water from the Mississippi river, *viz.*:

Enlargement and improvement of old works..	$415,000
Construction of new works in Third District..	600,000
Construction of new works in Sixth District..	590,000
Laying additional piping required.....	500,000
Total.....	$2,105,000

The Tangipahoa is a beautiful stream fed throughout by bountiful and never-failing springs of pure water, and passing for the most part through beds of clear gravel and white sand. It takes its source in the vicinity of Summit, Mississippi, a little more than one hundred miles from New Orleans, and after crossing the Louisiana State line, courses generally parallel to and a few miles distant to the eastward of the line of the N. O St. Louis & Chicago railroad, and finally empties into Lake Ponchartrain. The point selected at which it should be tapped is about five miles northeast of Tickfaw station, or opposite a point which is sixty-one miles from New Orleans, and one mile distant from the railroad. At this location a main retaining dam must be constructed with suitable wing levees, and so arranged that the water will be raised above its natural low water flow about fifteen feet, or sufficient to form a proper head for supplying the main *receiving* reservoir, which is designed to be constructed adjacent to the railroad at or about the fifty-six mile post. The connection between the receiving reservoir at the railroad and the dam on the river will be made by means of a canal with suitably embanked sides or walls, which will act as a conduit for the required quantity of water which is to be diverted by the dam from its natural flow or channel. This receiving reservoir should be constructed so as to cover about forty acres of ground and to hold at least ten days supply for the city.

When the water is raised in the river by the dam, as above proposed, its elevation will be about ninety feet above the ordinary street level of New Orleans, and this same elevation will be of course transferred and maintained in the receiving reservoir as a head or starting point for distribution through the iron piping leading therefrom into the city.

The volume of water passing in the river at its minimum or lowest stage has been calculated by recent measurements to be about one thousand cubic feet per second, or 648,000,000 standard gallons per day. This is deemed amply sufficient to furnish New Orleans with an abundant supply of water for all time to come, or for the largest population she can ever reasonably be expected to attain.

In connection with the dam, it will be necessary to construct a suitable lock, so as to regulate the influx of water during the freshet periods in the river, and to prevent that which would be discolored thereby, from reaching and contaminating the clear water already received in the reservoir. These interruptions would last at the utmost but a few days at a time, only during the prevalence of a rain storm, and within a few hours after its cessation the river would begin to subside and gradually become again perfectly clear, so that the maximum supply of water in the reservoir would be soon replaced and its normal condition regained before the occurrence of a second flood. It is for this reason, and to provide against such contingencies, that it would be necessary to construct the lock as proposed, and, also, to have the receiving reservoir built on the enlarged scale which has been designed.

The topography of the country and the character of the land is exceedingly favorable to the location, construction and maintenance of these several works, and a large proportion of the whole can be substantially executed by cheap earthen embankments, and therefore, only a small amount of expensive masonry will be required.

The cost of all these works combined is estimated approximately at $150,000.

From the main receiving reservoir to the city, it will require a line of iron piping to be laid alongside the railroad track, and for a total distance of about fifty-six miles. This piping should not be less than forty-eight inches in diameter, to answer the present demands of the city, and will cost at the rate of about forty thousand dollars per mile to be laid in position, or for the entire distance $2,240,000. It is calculated that this one line of piping will deliver about 12,000,000 gallons per day to the limit of the third stories of all buildings, or sufficient to supply the present daily wants of the city. At some future day whenever the population and demand for water increases, an additional line of piping can be placed alongside of the first one so as to enlarge the supply, and this, too, without increasing the capacity of any of the other works. The only physical obstacle which presents itself in the laying of the piping, is the crossing of about one hundred feet in width of the navigable opening in the railroad bridge at Pass Manchac, but this is not a difficulty which cannot be successfully overcome. If it were not for the existence of the railroad and the facilities afforded by it for getting the heavy piping in position, the Tangipahoa scheme would be impracticable, for there would be no way of overcoming the difficulties in crossing the intervening swamps, without first preparing a roadway at an

unwarrantable cost for transporting the different pieces to their destination.

It is proposed, also, as a matter of utility to establish at various points throughout the city, iron tanks or reservoirs of moderate capacity which may be termed stand pipes or vertical reservoirs, and each of which will be able to accumulate an additional column of water during the night or non-consuming portion of the twenty-four hours, sufficient to greatly accelerate the succeeding daily supply for that portion of the city contiguous to it, as well as to facilitate by proximity of pressure, the delivery of water to the highest practicable elevation.

We have, then, as an approximate estimate for the supply of water from the Tangipahoa river the following, *viz.*:

Construction of lock, dam, canal and res'vr,	$ 150,000
Iron piping 56 miles and laying same.....	2,240,000
Stand pipes or vertical reservoirs.	250,000
Expropriation, etc., of property required ...	25,000
Laying additional piping throughout city...	500,000
Total for whole.....	$3,165,000

Comparative estimates of original cost or first outlay for supplying New Orleans with a full and permanent supply of suitable water.

From the Mississippi River.....	$2,105,000
From the Tangipahoa River.....	3,165,000

I have not felt myself called upon in this communication to do more than present the facts and suggestions above recorded, without expressing an opinion, even in an engineering point of view, for the preference or adoption of one plan over the other, leaving this as well as the financial problem involved, and all details connected therewith to be discussed and decided by those who may be induced to co-operate with the city in the prosecution of the enterprise.

Respectfully submitted,

THOMAS S. HARDEE, *City Surveyor.*

NEW YORK UNDERGROUND RAILWAY

We take from the *City Record*, New York, the petition of successors of the New York City Central Underground Railway Company, asking for certain rights and privileges which is as follows:

To the Hon. Mayor and Board of Aldermen of the City of New York:

I most respectfully beg to ask, on behalf of myself and others, successors of the New York City Central Underground Railway Company, some temporary rights and privileges in streets and public places, as specified in the annexed schedule, in order to facilitate the work on the tunnels and railways which we are preparing to construct and operate. These facilities you are by the third section of chapter 230 of the laws of 1868, empowered to grant, and they will aid in establishing what has become the greatest public necessity as well as the most important improvement ever proposed for this or any other metropolis, not in the cost or magnitude of the work, but in view of its location and public advantages.

This is the construction of a railway out of sight and hearing, passing through the most densely occupied portions of the city, extending from the Battery to Eighty-second street and Madison avenue on the east side, with a branch from Union square under Broadway to the Circle at the southeast corner of Central Park. These lines will constitute the southern section of the Great Metropolitan Railway, extending over eight miles, with double tracks throughout, one mile more than twice the distance from the City Hall to Forty-second street, and can now be made complete at a cost covering all lands to be purchased and compensations to be made, under $7,750,000, and with scarcely a doubt for $7,000,000.

If $1,250,000 were added, as has been alleged was necessary for equipments, at the present price of locomotives and cars, over two miles—one-fourth of the whole length—would be compactly covered with rolling stock, too excessive for use. But equipped for 200,000 passengers per day, or over 60,000,000 per annum, so as be carried at a maximum speed of from 35 to 45 miles an hour, these great arteries of metropolitan communication, through the length and breadth of the population and to the core of business, will cost not more than $9,000,000, and less than you were recently informed would be required for the section from City Hall to Forty-second street, not half as long, and that can never give one-third the accommodation. The actual estimate of the cost of that section made by Mr. Buckhout for Mr. Vanderbilt in 1872, was not half the amount reported to you by Commissioner Campbell, although embracing $1,000,000 for purchasing land in that portion of the line running through the blocks from the Bowery to Centre street.

However important rapid transit may be for the four and a half million passengers who last year arrived at and departed from the Grand Central Depot, it is of at least ten times greater consequence to the community residing north of Forty-second street, and south of Ninetieth street, who will use this extension and branch, and who now give over forty-five millions of passengers annually to unsatisfactory appliances for conveyance. Stopping at Forty-second street, the great residential districts would be merely touched, but not provided with rapid transit, while these two limbs to the body of our work will make it a complete metropolitan improvement.

There will be three stations on Madison avenue north of the Grand Central Depot, and three on Broadway, north of Madison square, and an experience of fourteen years in London has demonstrated with absolute certainty that each one of these stations will supply as many passengers to the line as the Forty second street station, and probably more. There are several horse railroads where each half mile up-town receives and distributes more passengers than come and go to that station from the lower part of the city, and who count certainly not more than three millions in a year, the others coming and going from hotels and private residences up-town.

Now, rapid transit is wanted for the people of the City of New York, and not for strangers to get here; but if, for the latter when here, and these lines will afford complete facilities to the whole district between Third and Eight avenues, which supplies annually about one hundred millions of passengers to horse cars and omnibuses, showing the forty-five or fifty millions estimated for the whole line to be moderate, and yet ten times more than a country railroad can give.

Transporting city passengers by steam has for fourteen years been done in London in precisely the way that we are preparing to do it, the only way that is possible, and that has made it known to mankind. This is accomplished there with a speed, facility, and economy as much superior to horse-power, as steam is here superior to horses for conveyance in the country; but London has only about half the travel per square mile as is here.

Moreover, we now know that the capital for this whole work can be obtained with greater certainty and on better terms than for the section from the City Hall to Forty-second street, for the percentage of income will be much greater on the whole investment than for any section or part. The net earnings, after deducting every possible charge, will be not less than one million five hundred thousand dollars per annum, or seven per cent. on twenty millions of capital, over twice the amount required, and, to the shameful incapacity of this city, as we shall see, this has been demonstrated for years in London.

The extension under Madison avenue, for two miles north of Forty-second street, will pay on every rod of the line, and, in addition, it will have the very great value that, where the New York and Harlem Railroad will give one passenger down to the City Hall, this extension will give over two and probably three passengers more. Up to Ninetieth street, about the limit of dense occupancy on the east side, there will be as complete command of city traffic as if the New York and Harlem Railroad had no existence. No one is likely to go to the Fourth avenue for rapid transit on a broken line, when he can have it without break or transfer down to the extreme southern end of the city. The single neighborhood around the Forty-third Street Station will give more business than the Grand Central Depot.

Similar considerations, not to be disregarded, urge the construction of the branch on the west side, for, as we have seen, it must have an immense traffic. Together, they will give rapid transit to a population that now sustains certainly four, if not five, lines of horse cars, and three lines of omnibuses, which have a far larger capital, and incur four times the operating expenses. Experience has shown for a dozen years in London, that the work will be done incomparably better than by all these existing and costly appliances, and with three-fold greater profits.

Such is the economy of steam over animal power, that the most profitable steam railway would at once become bankrupt, if horses were substituted; a train drawn by a powerful locomotive, costing less to move than an omnibus or horse car. And so great is the concentration of city travel, averaging two hundred and fifty times more per mile on one horse than on the steam railroads of the State, and notwithstanding the great expense of animal power, the Third Avenue Railroad yet earns seven per cent. on the capital of $1,250,000. If these passengers were drawn by steam, it is demonstrated in London, as well as on our country steam roads, that the net income would be 7 per cent. on a capital of $3,000,000 per mile. The underground railway there, although charged with four, five, six, and on the last mile down town, as high as seven millions of dollars per mile for right of way, earns over 4½ per cent. on the whole capital, showing the enormous profits where no land is bought, and the great value of our right of way under streets, not to be had but in short pieces in London, and where, often, in getting to these, the extra cost is about as great as if they were abandoned. The approaches to the East river bridge show how great would be the expense of buying the way here, and the Fourth avenue tracks, if through private property, would have cost seventeen, instead of six millions, illustrating these charges in London. Even the land for, and for approaching the new Bergen tunnel, one part consisting of rock and the other of swamp and mud, unoccupied, has cost more than that great work itself.

By going to the Battery, all from every quarter up-town can reach Wall street by the Wall street station, giving renewed vitality to that national centre of business, and a greater value to extreme down-town property than has been known in the history of the city.

The work which you can thus aid, is not, therefore, to desolate the inside for barren outside districts, but it is for the benefit of the whole of the now paralized property, business, and population of the city of New York, for imparting new life and power from one end of the city to the other, so that it can expand into and over these now waste places, and sustain the burden of its great taxation.

Only since last October, after the legal transfer was perfected, has there been opportunity for capital to approach this great metropolitan improvement, because those controlling it, for the seven years before it came into our possession, were interested to secure its defeat, unless by mortgages for fabulous amounts and other devices, counter corrupt inducements could be presented for its progress. With these and gross exaggerations of cost, studied misrepresentations of practicability, and for suppressing all knowledge of the enormous profits, has the work been so long delayed. The same persons seduced credulous capitalists to waste some two millions in worthless rapid transit devices for no other object than to prevent this. The public has been slow to recognize these causes that have defeated rapid transit, but they are as veritable as the frauds of the ring.

The prostration of all other underground lines, by preserving and yet not using this grant, came from the fact, that it occupied all practicable routes between Third and Eighth avenues, Broadway, south of City Hall and north of Union square, and Fourth avenue, from Eighth to Fourteenth street.

In curving the line in and out of Fourth avenue, a competing line would be driven for such a distance under the blocks on the east side, as to add at least another million for land, besides the similar charge from the Bowery to Centre street. This was the real difficulty with the Vanderbilt grant which Mr. Buckhout, in his plans and estimates, tried at first to disregard. It was at least one of the causes, and probably the real cause of its abandonment. At the same time the Beach or Broadway charter was worthless as long as this was in its way. Capable of the greatest public benefits, our rights and franchises could yet be used to perpetuate existing evils, and to this they were dedicated by the previous managers, from whom they could be recovered only by long and persistently pursued legal proceedings. When this recovery was foreseen as inevitable, but before it occurred, some of the directors became a majority of Major Wickham's rapid transit commission, and the public will remember, kept that body in secret session under lock and key during its whole existence; and this is the local history of rapid transit.

Not three months since, this work might have been restricted to a mere extension of a country railroad to the City Hall as a concession for the capital to carry it out. But the necessity for this paralyzing limitation has now disappeared, and how fortunate for the future growth and grandeur of the city, the public can as yet hardly form a conception.

These arteries, throbbing with the life of the city, will be the first realization of the grand metropolis which is to emerge out of the load of debt and taxation, which makes recovery under existing conditions impossible. For any future but that of death, this city must be utterly different, vastly greater and more powerful than ever before, a result not of municipal charters or political tinkering, but of that mastery over material conditions which makes the distinction between barbarism and civilization, between the stone and iron age, between the era of animal and the era of steam power.

This new force on land and water, outside of and all around Manhattan Island, has overtasked its feeble motors, for there is a daily exaction of labor from that poor mechanical insect, the horse, such as is not found elsewhere on the earth.

The remedy is the work in which we are engaged, and it is now as certain to be made, as that we are not to relapse into barbarism. All that has been required for the last ten years, in order to have rapid transit, was to learn how it was to be had, there having been nothing in the way but the want of this understanding, and the conspiracy got up to maintain it.

With this combination broken, there are no serious difficulties to overcome, for capital cannot be kept away when the barriers so carefully erected and so long guarded, for preventing its approach, are removed. This is now substantially accomplished, for after years of effort to that end, this great gift of the right of way under streets, worth from two to three millions sterling if in London, is now available for use, and we entertain no doubt whatever of having, within a reasonable period, the work in a state of active construction.

But no one man, or ten, can do this without aid—the most potent controller of railroads never made even one; and, if the people of this city are to have a great metropolis they must share in the means and efforts for its attainment, which they will cheerfully do; and here is the first opportunity in this matter that has been presented. Very respectfully, your obd't servant,

O. VANDENBURGH.

Dated May 19, 1877, 229 Broadway, N. Y.

Schedule of Privileges in Streets and Public Places

for Constructing the Underground Railway asked for by the Successors of the New York City Central Underground Railway Company.

1. To deposit materials outside and south of the line of the works near the Staten Island Ferry, on the Battery.

2. Similar privileges on the north side of the street, between the Post Office and the City Hall Park, reserving sufficient width of roadway for vehicles to pass each other through the whole length of the street.

3. Similar privileges at the junction of Worth, Baxter and Park streets, with a like reservation of passage.

Similar privileges on the northerly and southerly borders of Union square, on ground outside the square and not within the boundaries of streets.

5. The same privileges at the Circle, southwest corner of Central Park, and in streets crossing and near Madison avenue, where no houses are erected on the lots abutting against the streets where the materials are deposited.

These privileges to be revokable by the Mayor and Board of Aldermen, and subject to regulation by the Commissioner of Public Works.

O. VANDENBURGH.

Which was referred to the Committee on Railroads.

TIDAL WAVES ON THE LAKES.

The Cleveland *Herald*, in connection with the tidal wave reported from Port Stanley, Ont., gives the following interesting information :—

Tidal waves on the lakes are not of uncommon occurrence. In fact they occur on all lakes and seas, without visible cause. Two or three years ago Col. Chas. Whittlesey, who had given the subject much attention and collected a large amount of information concerning it, read before the American Association at Hartford a paper containing detailed accounts of such tidal waves or "swashes" on this chain of lakes as had been noticed and recorded.

The first noted on Lake Superior was in 1789, when Alexander Mackenzie saw at the Grand Portage, on the north shore, opposite Port Royal, a sudden fall of water, equal to four feet, which soon returned with a rush and continued to vibrate several hours. In 1834, the water above the Sault suddenly fell two and one-half feet, and in half an hour came surging back with great velocity. In 1842 the same thing happened below the falls the current of the river rushing swiftly up stream. Dr. Foster has placed on record that in August, 1845, whilst in an open boat on Lake Superior, between Copper harbor and Eagle River, he saw a huge wave, twenty feet high, suddenly rise in the lake, about a quarter of a mile distance, which curled over like an immense surge, crested with foam, and swept toward the shore, diminishing as it advanced. It passed the voyagers without doing them an injury, was succeeded by two or three swells, and after spending its force on the shore the lake resumed its calm. In 1847 and the two following years Dr. Foster observed similar phenomena. A sudden rise of one foot three inches was observed at Copper harbor in November 1851. In July, 1855, there was a succession of rises and falls at the Sault from nine in the morning to four in the afternoon, the maximum of variation being two feet two inches At Superior City, on the 22nd of September, 1865, there was an oscillation of fifty inches in fifteen minutes.

On Lake Michigan Father Andre reported in 1670 there was on Green Bay a sudden change of three feet in the level of the lake, which left his canoe high and dry. In April, 1858, a wave rushed into the river from the lake with such violence that the ferry boat on the Menominee was upset. There was a sudden ebb, and in about twenty minutes two larger waves came and receded. The difference in about three quarters of an hour was full six feet.

Tidal waves on Lake Erie have been numerous and violent. It is supposed that the loss of Col. Bradstreet's expedition off Rockport river, in October, 1761, was due to a sudden "swash" similar to one observed at the same place by Mr. Taylor in 1811, when a white crested wave rushed in from the calm lake and carried a barrel of salt several rods over what had been dry ground into a ravine. DeWitt Clinton reported that on the 10th of May, 1823, at Otter creek, on the Canada shore of Lake Erie, when the water was calm, a wave nine feet high swept over the beach into the woods and stranded a thirty-five ton schooner. The same thing occurred at Kettle creek, twenty miles distant. In the spring of 1830 Mr. Luther Winchell, of Lake county, was fishing with three others at Madison dock, when three large waves came rolling in and swept the party inshore. The first wave was fifteen to twenty feet high, and the succeeding ones of diminishing height. Fourteen years later a wave fifteen feet high swept into Euclid creek, carrying everything before it. On the 19th of November, 1845, the water registers of Colonel Stockton, at Cleveland, showed a sudden fall of two feet eight inches. In December, 1856 the level of the water at Toledo changed in a few hours ten feet, first rising five feet above the ordinary level, and then falling five feet. In this case, however, the oscillations followed a change in direction of a strong wind.

With the last mentioned exception none of the sudden changes of level were accompanied by or followed strong winds. In nearly every case the sudden rise or fall of water occurred when the air was still and the lake perfectly calm. In many of the cases, especially those of oscillation, the "swashes" were followed by storms. This fact, which is true of similar oscillations of level in large bodies of water in other parts of the world, suggests a possible explanation of the phenomena. The tidal wave is said to come in from open water parallel to the shore. May it not be caused by a sudden atmospheric disturbance, or wave, which is local in its extent? This merely a suggestion, for scientists who have given time and study to the matter commit themselves to no definite theory.

THE WILKES-BARRE MEETING OF THE INSTITUTE OF MINING ENGINEERS.

The American Institute of Mining Engineers has held this week in Wilkes-Barre its sixth annual meeting. Organized in the same place in 1871 by a small gathering of twenty-two, its numbers have now increased to seven hundred, and its usefulness and influence are felt not only throughout this country, but also in Europe. Many interesting and valuable papers were presented at the meeting, some on subjects which have not hitherto been brought before the Institute, as Mr. Bowie's paper on Hydraulic Mining in California, and Mr. Keith's paper on the Transmission of Power by Electricity. The accession to the membership was thirty-five. The local committee arranged an admirable programme of excursions, whereby the interesting features of the Wyoming Valley above and below ground were shown to the members under the guidance of Messrs. Mercur and Stearns. The officers elected are as follows:

President, Dr. T. Sterry Hunt, Boston; Vice Presidents, Thomas Eggleston, New York; John B. Pearse, Boston; W. P. Shinn, Pittsburg; Managers, E.T. Cox, Indianapolis; H. S. Drinker, Philadelphia; A. L. Holly, New York; Treasurer, Theodore T. Rand, Philadelphia; Secretary, Thomas M. Brown, Easton, Pa.—*The Engineering and Mining Journal.*

CORRESPONDENCE.

BEAVER CROSSING, SEWARD CO., NEB., *May 21, 1877.*

Editor ENGINEERING NEWS.

SIR — Will you please inform me of the legal manner of establishing a lost section corner? If one person on a section desires to have the section surveyed, can he oblige those cornering with him to help pay for the survey? Does a county surveyor's work out of his own county amount to anything in law?

G. A. K., *County Surveyor.*

To establish a lost section corner, the east and west, and north and south section lines must be chained between the two nearest undoubted corner posts; divide these measurements *pro rata* with the Government distances given on the plat and establish the missing corners therefrom.

We understand that in some states, by giving due notice according to law, the parties whose lands have a common corner or boundary, are obliged to share the expense of the survey. We think this is the law of Indiana, but we do not know positively whether it is or not. It is a difficult matter, however, to compel adjoining owners to share the expense of a survey; there is always one party who, feeling certain that he has a little more than his own, will refuse to do anything to assist in the location of boundaries. It depends in what State the county surveyor may be practicing whether he can make legal surveys in counties outside of his own. In Illinois his survey is legal in any part of the State if he can prove himself to be a "competent" surveyor; if he can satisfy the owners of adjacent lands between which he runs a line in any county in America, his survey is legal by their mutual agreement.

NEW ORLEANS, *May 23, 1877.*

Editor ENGINEERING NEWS:

SIR.—In your issue of May 19th, there appeared a letter from W. H. Bell, C. E., which criticised somewhat intemperately the re-publication in your journal of an article formerly prepared by me on the drainage of New Orleans.

As Mr. Bell has felt himself professionally aggrieved and has indulged in some insinuations and reflections considered unjust to me, I feel compelled to submit a brief statement of facts in reply.

In the first place, the recent publication of the article with accompanying map in your paper was made through the instrumentality of my successor, Mr. D' Hemecourt, the present City Surveyor, or one of his assistants, who delivered the map plate, which was city property, to your editor on his request, while recently in New Orleans, and was not accomplished through any agency of my own.

The original publication in the *Sanitarian* was brought about through the instrumentality of the then president of the Board of Health here (Dr. White), who had received from the editor a request for a description of the drainage of New Orleans, and at the earnest and repeated solicitations of Dr. White the article in question was prepared.

I did not feel myself called upon to do more than to describe the situation as it existed, as the accredited engineering officer of the city, and not to eulogize Mr. Bell or any one of the many other local civil engineers who had previously participated in maturing and recommending the plan of drainage which had been adopted. I certainly did not take any credit to myself in the article for being the projector of the system, or for having performed any special services in connection therewith, and as a refutation of any charge in this direction, I would simply state that the pronouns *I* or *my* cannot be found once in the entire article. My principal aim and object was to make a plain recital of facts for those who had solicited the information, with such other suggestions relating to the subject as I thought would be of interest to the general public.

As to the attempted satirical remark of Mr. Bell in reference to my being a "map copyist," and the charge that I had plagiarized from the plan prepared by him, I assert that my drawing was in every respect an original one, designed from the same public data possessed by him, with many more details embodied upon it, differing in every respect that it is possible for any two things to differ, prepared by different persons on the same subject.

Mr. Bell states also in a spirit of disparagement, that my connection with the drainage of the city under *his* system was only for seven months, but with due deference to his accuracy as an engineer, it will be well for him to refresh his memory, and he will be compelled to acknowledge his error, that from the time of my accession to office as his successor, in December 1874 to the month of July 1876, when the work was suspended, there is an aggregate of nineteen instead of seven months.

I have written this only to defend myself against the imputation of professional discourtesy, and until I am convinced that the failure to unduly eulogize is a breach of professional etiquette, I have nothing to regret in the publications which have been made under my name with regard to the topography and drainage of New Orleans.

Very truly,

THOMAS S. HARDEE, C. E.

BOOK NOTICE.

The Forces of Nature. Part 1: A popular Introduction to the study of Physical Phenomena, by Amedee Guillemin; translated from the French by Mrs. Norman Lockyer, and edited with additions and notes by J. Norman Lockyer, F. R. S. Illustrated by nearly Five Hundred Engravings. London and New York: Macmillan & Co. 1877.

PROSPECTUS.—The "Forces of Nature" has hitherto been accessible in England only in an expensive edition in one large volume. It appears to the publishers that by issuing it in monthly parts, at about half the original cost, they will bring it within the reach of a wider circle. They believe it is not too much to say that there is no work in the language from which the general reader can obtain a clearer view of the principles of physical science, and that it is as sound and accurate as it is popular. The number and beauty of the illustrations, and the lucidity of the style, have given it an enormous circulation in France, and two very large editions have been sold in England. The whole book has been thoroughly edited and adapted for the English public by Mr. J. Norman Lockyer, F. R. S., whose name is a guarantee not only for the scientific accuracy, but for the completeness and lateness of the information.

The first of the seven books of which it consists treats of Gravity and Attraction, the weight of air and gases, the pendulum, the balance, and the barometer. The second discusses the phenomena of Sound, propagation of sound in air and tubes, and the theory and explanation of musical instruments. The third of the laws of Light and Color, phosphorescence, double refraction, diffraction, and polarisation. The fourth book is devoted to Heat. The fifth and sixth to Magnetism and Electricity, and the seventh disscusses the rainbow, the rise and fall of clouds and fog, and the whole subject of Atmospheric Meteors. There is a very complete and elaborate index to the work.

The First Part will be issued on May 1, and the publication will be continued Monthly, the whole being completed in Eighteen Parts.

The *Daily News* says:—"The method of pictorial illustration, accompanied as it is by descriptions of singular clearness, makes the experiments as easy to understand as though they were actually performed before the reader. There are 450 of these illustrations, all well executed, and so admirably fitted to the text as to make the book interesting to young people, while it is at the same time worthy of the notice of the student."

The *Saturday Review* remarks:—"Altogether the work may be said to have no parallel either in point of fulness or attraction, as a popular manual of physical science."

It is with genuine satisfaction that we introduce to our readers this valuable and interesting work. The prospectus, which we give in full, tells the story, and we can say that, judging from the very popular style in which this first part is written,—so free from mathematical formulæ, and so simple, that it must recommend itself to every observer of the laws of nature, and especially so to a large portion of the readers of this journal, who, while they have perhaps been accustomed to studying physical science with the aid of the higher mathematics, are yet not averse to reviewing the same truths

in a popular form when presented by such a master as J. Norman Lockyer. The pages are seven by ten inches in size, the typographical execution is exceedingly fine, and, being very profusely illustrated, the book when complete will be an acquisition of genuine value to the library of any student. The parts are 40 cents each, and for sale by Hadley & Bros., of Chicago.

Zeitschrift des Architekten-und I genieur-Vereins zu Hannover. Hanover. 1877.

Experiments and Observations on the Emission of Heat by Hot Water Pipes. By William Anderson, M. Inst. C. E. Transactions Institution of Civil Engineers.

NOTES.

The question of water supply is rising in Owen Sound, Ont.

The Norwalk Shoe Factory will do a business of over $100,000 this year.

Large beds of fire clay and block coal are being developed in Ellsworth, Mahoning County, O.

The Keystone Bridge Company has made a bid for a bridge to be erected at Cleveland. The structure will cost about $80,000.

The Swedes are building gun-boats for Russia in sections so that they can be readily transported to a distance and quickly screwed together.

Recent incorporations in Ohio, with their capital stock: Security Lightning Rod Co., Canton, $100,000: Quaker Mill Co., Ravenna, $25,000; Alliance Co-operative Association, $350,000.

A new stone arch county bridge at Centre Valley (Lehigh county?) lately fell down. The structure was 130 feet long and 30 feet high—cause of falling, faulty construction.

Joseph G. Kirk, civil engineer, has been appointed to the position of Corporation Engineer for the town of Guelph, Ont., at a salary of $800. Mr. Kirk is an old resident of Stratford.

The officers of the Missouri Valley Bridge Co., at Leavenworth, Kansas, are Mr. E. J. Farnsworth, President; Mr. D. E. Eaves, Secretary and Treasurer; and Mr. H. A. Wise, Engineer.

The mines down the Ohio valley are rushing out coal beyond the capacity of the C. & M. R. R. company to carry. At Vienna junction there were 150 cars at a time nearly every day last week.

The Baldwin Locomotive Works, Philadelphia, have just closed a contract for 19 locomotives for Brazil. Fourteen of these are for the Dom Pedro II. railway, and five are for a narrow gauge road.

The grading for the additional tracks to the Pittsburgh, Cincinnati & St. Louis R. R., from Ogden avenue, Chicago, to the Stock Yards, has been let to John McAffery, of Brighton, Ill; masonry and timber work to the Chicago Dredging and Dock Company, and the Iron superstructure for two bridges to the Detroit Bridge and Iron Co., of Detroit, Mich.

A Ledge has been discovered in Lincoln, R. I., within two miles of the village, which promises to be of great value. An essay of some of the quartz shows that a ton contains 1456 pounds of lead, 64 ounces of silver, and 40 pennyweights of gold. The specimens that have been taken from it, are said to be by far the richest in metals of any ever found in New England.

May 22nd, Gov. Robinson of New York vetoed the items in the Supply Bill appropriating money for building eleven iron bridges out of the canal fund; also for repairs for the Cheeming Crooked Lake, Chenango, and Black River Canals, "for the reason that the work is not absolutely necessary, and the canal revenues are not likely to be sufficient to warrant the doing of any work that can safely be dispensed with."

Heavy rains in the West have caused a rise in all the rivers tributary to the Missouri and Kansas, causing serious interruption of railroad traffic and damage to the lines. A large area of country is liable to inundation if the river banks give way. As it is the rise of the waters is greater at Lawrence than has been known for twenty years. The recent warm spell in the West has melted a great deal of snow on the upper watersheds of the rivers, and this, with the heavy and continuous rains, has contributed to swell the floods pouring down into the low, flat valleys approaching the Mississippi River.

A cable dispatch from London announces the death of Matthew Digby Wyatt, the well known English architect. Mr. Wyatt was born in 1820 near Devises, his father being a police magistrate. At sixteen years of age he entered the office of his brother, Thomas Henry Wyatt, architect, and in the same year he gained a prize for an essay from the Architectural Society. Some years later he went to the Continent, where he studied the principle art monuments of France, Germany and Italy. In conjunction with Mr. Jones and Mr. Wild he greatly assisted in the settlement of the plan of the great Exhibition Building in Hyde Park in 1850. He was the author of a great number of important works on architecture. In 1855 he received the Legion of Honor.

Our citizens who can look back with a shudder at the inexpressibly filthy condition of the streets of Chicago the close of the past winter will doubtless take a deep interest in the process by which the London thoroughfares are kept clean all the year round. When one thinks of the topography of our city, and the way in which nature but asks the smallest assistance to keep the surface clean, he is filled with indignation to think how incompletely even that little aid is given. London, with its seven thousand miles of streets, rained on twelve months of the year, traversed day and night by tens of thousands of heavy vehicles, and trodden by its nigh four millions of people, yet manages to scoop up its mud daily over the entire surface, removes all its ashes and garbage with clock-like regularity, and so keeps down the death-rate even in the most densely populated districts to a surprisingly low figure. We can do the same and, proportionately, with a tithe of the same effort. It is a mere matter of business, and susceptible of the same economic treatment as the sweepings of a tobacco factory, where nothing goes to waste. Fortunes are made by doing the work in London.

The sub-committee of the Stock Exchange, appointed to secure reports from railroad and other corporations whose securities are quoted on the list, have made a report of the result of their labors, which is only encouraging from the probability that it will rouse stockholders to a proper sense of their rights and duties. It says the coal railroad companies excused themselves from reporting more than once a year, on the ground that being miners as well as carriers they could not tell where they stood oftener than once a year. The President of the New Jersey Central gave them clearly to understand that he would give no more information than the law obliged him to give, and said the public was satisfied with his reports, a belief which subsequent events rudely disturbed. The Michigan Central reported manfully while the returns were favorable, but no longer. The Milwaukee & St. Paul did the same thing. The Northwestern & Rock Island were absolutely uncivil in their replies. The Committee say they were discouraged a good deal by all this, but still more when they found that some reports, even when "signed and sanctioned by men of wealth and reputation," were often utterly untrustworthy. They therefore felt in no humor to make any report at all, but say that events have since occurred, meaning the tumble of stocks, which have gone far to accomplish the desired end. The fact is that concealment about the condition of corpo ations can have only one object—namely, the aiding of speculators, who are too often the directors themselves, either in getting rid of their shares before their real value is known, or borrowing money on them at a valuation much above their intrinsic worth. Both these things are forms of fraud, and of atrocious fraud when committed by trustees; and it is high time that it was stopped by stringent legislation, and the breed of autocratic, secretive, speculatiing cozening presidents and directors brought down to their proper place as holders of important trusts both for the public and individuals, and made to reveal the results of their administration as regularly and as fully and comprehensively as if they were accounting for the outlay of a sum of money given them for specifieu objects.—*N. Y. Nation.*

RAILROAD NOTES.

The Evansville, Owensboro & Nashville R. R., Ky., was sold to the bondholders on May, 29, for $60,000.

The P. D. & L. H. Railway Company Ontario., commenced repairing the harbor and building coal docks at Port Dover.

The Kansas Central Narrow-Gauge R. R. will be extended shortly from its present terminus, Nolton. The contract for building twenty-five miles will soon be let, and the work rapidly pushed forward.

General Superintendent Clark, of the Union Pacific, states positively that they will build one hundred miles of road towards the Black Hills this summer. The point from which the road will start is yet undesided; it will be either Sidney or Cheyenne.

The completed section of the Emlenton & Shippenville R. R., from Emlenton, Pa., to Edenburg, is reported as doing a very large business. A contract has been let for an extension from Edenburg west to Clarion, about 15 miles, the work to be finished by Sept. 1.

On the Hamilton & Northwestern Railway, between Georgetown and Barrie, Ont., there are employed at present nine hundred and ninety-two men, two hundred and sixteen teams, and sixty-one cars. The work on this division is being pushed forward with great vigor.

The remaining mile of track on the Dayton & Southeastern road, between Xenia, O., and Dayton, has been laid and the rest of the track put in good order, and on May 18 the first through train ran from Dayton to Washington Court House, 47½ miles. Regular trains will run hereafter.

The Canada Southern R. R. Company is building a grain elevator at the St. Clair river terminus of its St. Clair terminus, twelve miles below Lake Huron and Sarnia, which is to be completed by September. When completed the Commercial line of propellers will run between Chicago and this terminus, giving a favorable lake-and-rail-route.

Tracklaying on the Rochester & State Line R. R. was resumed at Pearl Creek, N. Y., May 7. Track reached Wyoming village on the 11th, and is progressing rapidly toward Warsaw, and will reach that place shortly. The road will be open for traffic to Warsaw June 15, and to Gainsville, 53 miles from Rochester, by Aug. 1.

There is talk of some action being taken in reference to building the proposed narrow gauge railroad from St. Louis Mo., to Colorado. A meeting is about to be called to effect an organization for the purpose of building a road. An enterprise that promises so much for St. Louis and the territory along the route, and which can be so easily put through, should be begun without further delay.

The last act of the long litigation concerning the title to the Kentucky Central R. R. took place in Covington, Ky., May 15, when the stockholders of the old Covington & Lexington Company met and voted to accept and ratify the compromise of 1875, which settled the once apparently endless suit of the Covington and Lexington Company against the Bowler heirs. The vote cast was 21,533 shares for accepting the compromise to 443 against it.

About one hundred men have arrived from Quebec, Canada, to work on the extension of the Quebec Central Railway through Garthy, and more are expected. A Quebec paper asserts that the company have decided to connect with the Grand Trunk Railway somewhere above Point Levis, while another says that a prominent capitalist of that city has agreed to advance the money required to connect with the Levis & Kennebec Railway at Ste. Marie de la Beauce. Five thousand tons of rails have been bought for the road by Messrs. Reed Bros., and will be shipped early this month on very advantageous terms.

Arrangements have been completed by the Chicago, Burlington & Quincy R. R. Company for building their extension in Chicago. The work consists substantially of widening the present grade so as to admit of two extra tracks being laid along side those at present existing, the new tracks only diverging sufficiently to allow of the swinging clear of the new bridges over the river and canal, which the present addition necessitates. The work commences at the point of junction of the Pittsburgh, Cincinnati and St. Louis R. R. with the North-Western, at Ogden avenue, and runs south to the Stock Yards junction with the P. C. & St. Louis R. R. The grade will be the same height as the present one; the piers of the bridges are to be built of stone masonry, with iron superstructure. According to present anticipations the work will be completed ready for use by the fall of the present year.

A French engineer has proposed to establish tramways with granite tracks in lieu of rails, in Finisterre. He is of the opinion that this system is far preferable to the ordinary railroads. There already exists a vast network of what are in truth tramways with granite rails, worked by horse traction, in Northern Italy. In the streets of the principal towns, and sometimes on the roads, tracks of granite are laid in the highways. The surface of these tracks being flat and perfectly smooth, the wheeels of the vehicles glide over them with the least possible friction. The conductor of each vehicle takes care so to guide it that the wheels always remain on the granite. The author of the project maintains that there is nothing to prevent the granite lines from being used by carriages driven by steam power, in like manner as though drawn by horses. At the same time it is not proposed to adopt the train system on granite tracks; each carriage will be provided with its own steam power, will move by itself, and be guided by means of a mechanism specially devised for the purpose.

The Aurora, Ill., *Beacon* says that the Chicago, Burlington & Quincy Company requires all material of whatever kind, to stand a thorough practical and scientific test before being delivered to the locomotive car or track depots. All boiler material is tested by bending while cold, which it must do without showing a flaw, and by getting the tensile strength of every sheet. Every sheet of iron for fire-box use must stand a tensile strain of 60,000 lbs. per sq. in. Every sheet of boiler material not for fire-box use, must stand a strain of 55,000 lbs. per sq. in. Every sheet of steel for fire-box use must stand a tensile strain of 70,000 lbs. per sq. in., and no sheets of iron can be issued from the store without being marked "Tested, O. K." All stay-bolt iron must stand 60,000 lbs. per sq. in., and bend double cold without showing any flaw, and a bolt ¾ in. in diameter must bend double cold, with a thread cut on it, without showing cracks more than ⅓ of an inch in depth. All common bar iron, whether round or flat, must bend double cold without showing a flaw deeper than ⅓ in., and bend double red hot without showing any tendency to "red shortness." All flues or boiler tubes must be of maker's weight, not less than No. 13 (wire gauge) in thickness, nor greater than No. 11; must caulk into a flue sheet without cracking or showing any seams in iron; must flat down and bend double cold without showing any flaw or crack either across or lengthwise of flue, and must show a homogeneous material when subjected to an acid bath.

THE SCIENCE OF ROAD MAKING.

BY CLEMENS HERSCHEL, OF BOSTON,

Civil Engineer, Member of the American Society of Civil Engineers.

[THE AUTHOR'S ADDITIONS TO THE ORIGINAL ESSAY ARE SET IN SOLID TYPE.]

INTRODUCTION.

An apology and explanation from the writer to the readers of this reprint would seem to be proper, showing the reason why he has allowed this Essay to be re-printed, with only a few notes in the way of additions, rather than enlarge and entirely re-write the whole. He was conscious of its many short-comings at the time it was first written in 1870, in the evenings of some twenty-five or thirty days. Subsequent experience as Superintendent of streets in two towns, and as a Civil Engineer, has, of course, only served to increase this feeling; and at one time it was his intention to use this Essay as the mere starting point for the composition of a little treatise on the Art of Road Making, for the use of Engineers and others, and considerable material was gathered together for that purpose. But other business intervened then; and now, when the publisher of ENGINEERING NEWS having signified his intention of re-printing the Essay, the writer finds that all the time that he can devote to writing on Engineering subjects is so fully taken up, that he cannot undertake to revise, remodel, and enlarge this essay as he would like. But rather than do nothing at all, he has added a few notes, which, it is hoped, may not prove unwelcome to the readers of this Essay, and of ENGINEERING NEWS.

This treatise was written in answer to the printed circular of a Committee of the Board of Agriculture calling for "treatises upon the science of road-making, and the best methods of superintending the construction and repair of public roads in this Commonwealth."

This circular was issued about the middle of December, and as the time for writing and sending in the called for essays was limited to January 28, the writer has thought it best, no specific character being prescribed for the treatises, to attempt to write one suitable to be so called from the stand point of the *public*, rather than from that of the Civil Engineer, and, giving results rather than the methods of arriving at them, to be as concise as possible.

THE SCIENCE OF ROAD MAKING.

Starting, then, with the first of the two subjects mentioned in the circular,—the science of road making, we can divide this into three periods: 1. Laying out a road; 2. making the road-bed, which includes all earthworks, cutting and filling, culverts, drains, bridges, even tunnels, etc.; and 3. the making of the road surface; to which, not improperly might be added, 4. keeping the road in repair.

LAYING OUT A ROAD.

The considerations which determine the best location of a road, are those arising from the nature of the travel it is proposed to accommodate; that is, from the admissible grades, radii of curves, etc. Given two points it is desired to connect, with no intermediate point where the road is to touch, that route is the best which will cost least to build and maintain, the grades and curves being kept within bounds; and to find this location constitutes the whole problem of the engineer.

In older countries, where trade and manufactures are more settled and unchanging than in the United States, the probable future travel upon a road about to be laid out and built, forms a material element in the data that govern its alignment and grades. A very able and clever article upon this subject may be found in the Journal of the Society of Civil Engineers and Architects at Hanover," for the year 1869, and also in pamphlet form. It is in the German language, written by Launhardt, Superintendent of Highways (and a civil engineer) in the Hannoverian provinces.

The Romans built all of their roads in perfectly straight lines, up hill and down, at a very great expense, as being absolutely the shortest distance between two points. At a later period in history, it was argued that a road *must* be winding to be agreeable, and many were so built only for this reason. The modern road-builder or engineer in general, ignores any such considerations, and has for his aim only to achieve the most, at the least present and future expense.

As regards curves in roads in a hilly or mountainous district, we have then the rules never to make a smaller radius than 20 feet, and that only in extraordinary cases. On roads where long logging or other wagons may be expected, the smallest radius ought to be 50 or 60 feet; and, in general, 40–45 feet is none too much.

A rule sometimes followed in constructing mountain roads, is, where the inclination is 1 or 2 in a hundred,† heavy teams require 40′ and light ones 30′ radius; with a grade of 2 or 3 in a hundred, heavy teams require 65′ and light ones 50′ radius. Where a reverse curve [shaped like the the letter S] occurs, there should be a straight piece connecting the two curves [Fig. 1.] On the contrary, where the two curve to be connected are concave in the same direction, the connecting link should be curved also, and not straight. [Fig. 2.] On the length of the curves the grade should be made easier than on the parts of the road immediately adjoining.

Fig. 1.

Fig. 2.

As regards grades, to start with mountain paths, we find pedestrians able to walk up an inclination of 100 in 120; mules, ponies, etc, 100 in 173. For roads, Telford's rule was, that for horses attached to ordinary vehicles to trot up a hill rising 3 in 100, was equal to walking up one of a 5 in a 100 grade.

Experiments have shown that—

1. On a road falling 2 in a hundred, vehicles would run down of themselves.

2. On the same kind of road, but having an inclination of 4 in a hundred, light vehicles had to be held back lightly, loaded ones with considerable force.

3. On a road having a fall of 5½ in a hundred, light vehicles had to be held back with considerable force, or if a brake was applied they had to be pulled, whereas heavy or loaded vehicles had to be braked to keep the horses from being speedily exhausted.

On inclinations steeper than 5 in a hundred, the rainwater running down the road is apt to do some damage to the road surface.

The regulations of different countries having a long experience in road building, such as France, Prussia, Baden, etc., vary somewhat, but the following is the general result:

In treating of roads, it often renders the subject much clearer, to divide them into three classes: first, second and third class roads, or, as we might also say, state, county and town roads. Accepting this nomenclature, we have this: for first-class or state roads, the greatest inclination should not exceed 3–5 in a hundred; second-class or county roads, 5–7 in a hundred; third-class or town roads, 7–10 in a hundred. A road rising 10 in a hundred is not supposed to have any heavy teams upon it. In ascending a hill it is well and proper to decrease the grade as the top is reached, and in the same measure as the horses get tired. Thus, if a first-class road starts up hill with agrade of 4½ per hundred, it shouldgradually diminish to 4 and 3½ in a hundred, and end near the topwith a grade of 3 in a hundred.

Launhardt, the superintendent of highways, and engineer, mentioned in the previous note has a valuable article on the subject of the best grades for highways, in the Engineering journal there mentioned, for the year 1867; re-printed also in pamphlet form. He shows in this article that, according to the received formula that expresses the relations between the tractive force, the velocity in feet per second, and the daily working hours that go to produce the maximum amount of work that can be got out of a draught-horse, a uniform grade between any two points, except perhaps in curves, and, if desired, for resting places, is the grade that tends to enable the horse or other-draught animal to produce the most work per diem.

If a grade of 4 or 5 in a hundred must needs be kept up for some distance, then it is well to have resting places 40 or 50 feet long, having a grade of only 1½ or two in a hundred, in the line of the road at proper intervals. An expedient adopted by Telford, the eminent English engineer, in order to avoid making a piece of road a mile long, on a less grade than 5 in a hundred, on account of the increased cost this would have occasioned, and yet not have this part of the road too much more tiresome for the horses than the rest, was to make the road-surface on this mile of a much better quality than on the remainder; the additional cost required for the improved road-bed amounting to only about one-half of what it would have cost to reduce the grade to say 4 in a hundred, as will be again referred to under the head of trackways. In sharp curves the grade should be only 1 or 2 in a hundred or level.

To be continued.

*A First Prize Treatise awarded to the Author by the State Board of Agriculture, of Massachusetts.

† In describing grades, the first figure gives the vertical height which is ascended in a horizontal distance given by the second figure. Both figures must of course be taken to refer to the same unit of length thus: 100 feet in 120 feet, 100 inches in 120 inches, or 100 miles in 120 miles, all express the same inclination to a level plane, and are more general in their application than the ways of expressing grades in so many inches to the foot, or feet in one mile, etc., etc.

ELEVATION OF THE OUTER RAIL ON CURVES.

We have noticed with pleasure the comparison of opinions by the roadmasters of the Atlantic & Great Western Railroad, upon the subject which stands at the head of this article, at their last meeting in October, 1876. The chief engineer, Mr. Chas. Latimer, has established the excellent practice of calling together, annually, the subordinates of the engineering department, for a conference and discussion upon various points of importance with reference to proper maintenance of the permanent way. The system which he has marked out cannot fail to secure an excellent road, well and economically kept up.

The practice in regard to the super-elevation of the outer rail on curves is very various; on some roads no rule seems to be applied, or, if the application of one is attempted the elevation is guessed at by the eye, without the use of a level. If the track-men are ignorant of the degree of a curve, and do not know how to find it by measurement of a middle ordinate, any rule is useless. Some roads elevate proportionately to the degree of the curve; some raise the outer rail less in proportion for a sharper curve, and on different lines the elevations range from one-half to one and one-half inches per degree, with a greater elevation on lighter curves.

If it is intended to just balance the centrifugal force by elevating the outer rail, the practice would be reduced to uniformity as soon as the speed was the same. But as freight trains at fifteen miles per hour, and express trains at from forty to sixty miles per hour, develop an amount of centrifugal force varying as the square of the velocity, there is a difficulty in deciding what speed to assume as a datum. Henck's Field-Book states that the usual practice is to adopt the highest customary speed of passenger trains, and his formula is:—

Elevation in feet equals gauge in feet multiplied by the square of velocity in feet per second and divided by 32.2 times the radius in feet.

This formula is then modified so as to contain the velocity in miles per hour and the degree of the curve.

The formula stated to be used in England by the best authorities is the same in a little more convenient shape, namely—Gauge in feet multiplied by square of velocity in miles per hour divided by radius in feet,—this multiplied by four-fifths will give the elevation in inches. If Bogie trucks are not used an additional cant of 7,200 divided by the radius in feet should be added to the above.

Mr. Latimer has adopted the rule for the Atlantic & Great Western Railroad, of elevating the outer rail ¾ inch per degree for those parts of the line where the gauge is 6 feet, and ½ inch per degree for the gauge of 4 ft. 9¼ inches, the speed being taken at thirty-five miles per hour. This is intended as an average between fifty miles per hour for passenger trains and fifteen miles for freight trains, and the results are somewhat less than those obtained by the above quoted formulæ. Mr. Latimer argues as follows in regard to his own road:—

"With such disparity of speed, and with but one track, it becomes of vital importance to decide upon the question of elevation in its bearings upon the points both of economy and safety. Upon a road having heavy grades and curves, the question is a more serious one than that on those of level grades and similar curves. As the freight trains are from three to five times as numerous as the passenger trains, it is important that the elevation of the outer rail should be calculated somewhat in consideration of their speed. If the elevation is made for the full measure of the highest speed of passenger trains, which run only one-fourth as often as the freight, may we not have it so great that the freights will be in danger of running off on the inside of the curve? Again, since the elevation of the outer rail has a tendency to retard the progress of the train, may we not, by using too much elevation, cause such a diminution in the power of the engine as to shorten up the train and haul fewer cars? This is not only theoretically but practically the case, and, should the elevations be made for forty-five miles per hour instead of thirty-five, it would probably cause a dropping of a car in each train, and result in the loss of at least one train per day. It is, therefore, essential to consider whether it is not wise to equalize the elevation, so as to avoid, as far as possible, the danger from too great an elevation for the low speed of freight trains and the two slight elevation for passenger trains."

After an immunity from such accidents as can be ascribed to want of proper elevation, comes the comparative wear of the outer and inner rails on curves as a good test of any rule for elevation. On few roads, we surmise, is careful note taken of this fact. The roadmasters of the A. & G. W. R. R. agree that the curves, when put up by their rule, wear in about the same way as on a straight line, though more in amount, and that the inside and outside rails wear evenly. One man excepts curves at the foot of grades where trains run very fast; there he finds most wear on the outside rail. Of course, in such locations, an increase of what is considered average speed will obviate the difficulty and, indeed, Mr. Latimer cautions his men to rather exceed a little the standard elevation than to fall below it. The introduction of speed gauges on many of the trains has had an excellent effect in preventing excessive speed at some points, and in producing an economical rate of working.

Careful observations and discussions on such points as the one we have referred to to-day, if generally instituted on lines of railroad among the officials of the engineering staff, would go far towards the establishment of uniformity of practice and towards settling many things in regard to which facts are of more utility than further theorizing.

THERE seems to be a disposition manifesting itself among railroad men in favor of larger car wheels, it being proposed to substitute 42-inch wheels in place of the present 33-inch ones. There has been no absolute reason for the adoption of the present standard diameter rather than another. A small wheel enables the centre of gravity of the car to be kept low; they cost decidedly less than larger wheels, and weigh less. The cost of a 42-inch wheel is put at a little more than three times that of an ordinary chilled, cast-iron wheel, and its weight will be about 800 pounds. The centre of gravity of our present cars can undoubtedly be kept at about the same height, even if the diameter of the wheel is increased nine inches. The *National Car Builder* sums up the advantages of the larger wheels, as claimed by their advocates, as follows: "In moving a given distance, or at a given rate of speed, the number of revolutions is 21 per cent. less than that made by 33-inch wheels, and with a correspondingly diminished friction of journals and bearings; there is a saving of fuel resulting from a decrease of motive power consequent on diminished friction; the brasses wear longer and less lubrication is required; the bearing surface of the wheel upon the rail is materially increased; the average mileage is 2½ times as much as that of the standard 33-inch wheel; the annual renewals are less, and cars are less frequently off duty for that purpose; there are no hot boxes; the cars have an easier motion and are more comfortable for passengers; the wheels are stronger and safer, can carry heavier loads in proportion to dead weight of car, while at the same time there is considerable saving in maintenance of way."

ON THE MOUTHS OF THE DANUBE, AND THE IMPROVEMENT OF THE MOUTHS OF RIVERS IN NON-TIDAL SEAS.*

BY MAJOR STOKES, R. E.

(*Continued from page 143.*)

A strongly pronounced division of opinion ensued, the majority of the commission desiring to improve the southern channel called the St. George, according to the project of Mr. Hartley, the minority aiming at the improvement of the Sulina, the central and smallest branch, upon the recommendation of the Prussian engineer, M. Nobiling.

The researches of Mr. Hartley had established that of the three branches traversing the upper part of the Delta, the Northern or Kiliah branch contains 17-27ths of the volume of the river, the St. George's, or southern branch, contains 8-27ths, and the Sulina 2-27ths of it. The current of the river varies from one knot to three knots an hour; it has been known to be as high as four knots an hour, but that was for a very short time; the usual current is from one-and-half to two knots.

On two points unanimity of opinion existed, namely, in the rejection of the Kiliah branch, which discharging by five different mouths forming a minor delta, offered no hope of success; and in the adoption of the parallel pier system, as best adapted to the local conditions of the coast.

As unanimity of opinion was necessary, the points in dispute, after a discussion of five months, were referred to the governments, and by a portion of them submitted to the examination of another commission.

During the delay that seemed inevitable, the Danube Commission considered it advisable to give a temporary relief to the navigation by opening a passage through the bar at the mouth of the Sulina.

With this object it called upon Mr. Hartley to give a project for works to obtain an additional depth of two feet for a space of five or six years, that could be rapidly constructed at a cost repayable by the navigation in the interval likely to elapse before the permanent works should be open to trade.

This sum was estimated at about £40,000, and a project for that amount was submitted by the engineer and approved, the engineer stating, however, that he did not think it likely any appreciable improvement would be obtained with the limited extension given to the piers which he recommended, but that with an expenditure of £80,000, he believed that success would be almost certain.

He proposed to construct his piers of cribs filled with stones, and connected with strong piling. In the absence of any experience of works on the coast, and in view of the frequent bad weather, Mr. Hartley thought that this system could be carried out with more rapidity, with fewer obstructions from bad weather, and at less cost than any other.

Experience did not justify his predictions, but his skill speedily turned that experience to account, and produced a work that has more than answered the original intention. It was decided to construct the north pier first, as the prevailing winds blowing from the north, the south pier could then be carried out under the lee of the other. In April, 1858, the first piles were driven, and no difficulty was experienced in advancing rapidly in the shallow water. At the end of May the first crib was sunk in seven feet of water, at 900 feet from the root of the pier. This crib was formed of beams laid horizontally, and dove-tailed into one another at the angles, the cohesion of the structure being ensured by iron bolts and oak trenails passing through the beams and holding them together. The floor was fixed at two feet above the bottom of the sides, that these might settle down into the sands. The crib was successfully sunk, and filled and surrounded with stones; the following day as it was found to be sinking unequally, timbers were added to bring the upper surface above the water, and more stone thrown in, till it seemed firmly bedded in its proper position. On the 6th of June a heavy gale came on, and a heavy sea beat on to the crib which was exposed at some distance in advance of the piling; on the 8th the crib was seen to be slowly rising, and at length fairly floated away. As soon as the storm ceased it was recovered, and examination showed that the workmen had neglected to bolt the timbers together as directed, the sides only having risen, leaving the floor weighted down by the mass of stone. This, the only failure in the whole course of the works, is mentioned here as it led to the construction of cribs of a more solid description; the horizontal beams are tied and bolted together by bolts through them, and straps round them, while the frame is still further strengthened by cross beams through every second layer projecting beyond the sides, and again bolted and strapped together. On the 4th of October, a crib of this description, 30 feet long by 15 feet wide, and 14½ feet high, was sunk in 8½ feet of water, at 1,710 feet from the root of the pier, and up to this crib the skeleton piling was carried before the winter. This crib was successfully floated into position, and rapidly filled with stones and sunk; it was surrounded on the same day by 100 tons of large stones to protect it against the scour of the river current. During the four following days the weather was too stormy to admit of more stone being deposited, and in this interval the scour caused it to sink unequally at the four angles from 2 ft. 9 in. to 5 ft., or on an average 4 ft. On the fifth day a further 150 tons of stone was thrown down, and the crib was built up to the intended level of the pier. After finding its bed it never changed or sunk further, and most successfully resisted all the storms of the winter, acting as a buttress against which the waves broke, and thus so well protecting the unfinished skeleton piling, that no injury was sustained by the latter during the many months that elapsed before work could be resumed.

The piling was carried out as follows:—

---

*A Paper read at Chatham, England, October 16th, 1863.

Stage piles were driven from a light flat bottomed barge on which a ringing engine with a 5-cwt. monkey was fixed. On every available fine day the stage piles were driven on the line of the pier, keeping 100 feet or so ahead of the work; these stage piles were connected by cross planks on which rested the staging, whence the gauge piles were driven by a crab engine and 15-cwt, monkey. The gauge piles, in three parallel rows, of which the two outer were 14 feet apart, were driven at intervals of 7½ feet from centre to centre, and were tied together at their heads longitudinally by oak walings, 12 in. × 6 in., inside and out, bolted through and through, and transversely by cross stays 15 ft. × 12 in. × 4 in.; upon these transverse beams rested a roadway of pine planks, and an iron tramway for transport of materials. The gauge piles were of pine, obtained from the Carpathian mountains, in fine masts 80 feet long, and 2½ feet in diameter at the butt end. The sheet piles were at first of hornbeam, but subsequently of oak, as the hornbeam proved a very indifferent wood for water-works. The outer ends of the pier were constructed entirely of oak, of which fine straight piles 35 ft. × 1 ft. × 1 ft., were obtained from the forests of the Save.

The original project was to fill in the outer and inner line of gauge piles with sheet piling, and to fill the intervening space with stone, throwing down stone outside of each line of sheet piling at the angle it might take from the water line, to protect the foot of the piling from scour by the river current on the inside, and by the beat of the waves on the outside.

In the countries bordering the Danube, great difficulties were encountered in executing works, from the fact that no great works had been carried on there by the present generation, there were, therefore, no good artizans or even common laborers worth the name. Such contractors as were to be found based all their calculations on making enormous profits and fraudulent deliveries. Workmen unaccustomed to regular and fair payment, demanded a higher rate of wages than their labor was worth; the commonest was not to be had under half-a-crown a day, for less than half the work a good English workman would do. The Sulina works have produced quite a revolution in this respect, instead of having to bring workmen from Hungary and Transylvania, as in 1858, the Commission Works are now sought by more men than can be employed, who are ready to do a fair day's work for fair wages, because they have learnt that they are regularly paid to the day, and to the last penny due to them, and that to remain in employment they *must* do the work. The author has no hesitation in saying that the superintendence of English engineers and foremen has brought about this satisfactory state of things.

At first, however, great delay and many difficulties arose from the failures of the stone contractors to deliver stone of the size and quality required in the time stipulated; it thus frequently happened that the piling was far in advance of the stonework, and great scour consequently took place, leading to a far greater consumption of stone than was intended. Only the outer or seaward line of gauge piles was therefore sheeted at first, and stone thrown in to protect it.

During the first winter, which gave the structure a severe testing, the works stood thus: 1,390 feet of the pier were sheeted and protected by stone within and without to the level of the water, from thence to the crib the gauge piling was unprotected for 320 feet. The heavy break of the sea was in a great measure warded off by the crib, but nevertheless there was a considerable attack upon the remainder of the pier; this stood the assault so well that it was resolved to modify the original plan of the piling, and to sheet only the outer line, leaving the stone to take its slope from the water level on that line. The feet of the inner row of gauge piles were thus protected from all injurious scour from the river current, and it has been found that, although near the end of the pier, the stone goes down every winter, it is only packed closer down upon the sheet piling by the beat of the waves, and thus each successive filling in, in the spring, is adding to the strength of the pier at but a small expense.

The year 1858 gave a further experience, namely, that to give the cribs the necessary strength, their price became much enhanced, whilst the expected rapidity of construction to be obtained from them was not realised, on account of the difficulty of getting them safely into position, and filled with stone, before rough weather came on. The irregularity of the stone supply naturally contributed to increase this difficulty, but even had stone been abundant cribs could not have been sunk with the rapidity anticipated, nor could workmen have been found to build them; moreover, it was found that the piling proceeded with a rapidity beyond the most sanguine expectations, and was limited only by the insufficient supply of stone; it was only when the weather was very bad indeed that the pile engines could not go on with their work. It must be borne in mind that the absence of tides was an important advantage to this system. The cribs proved highly successful as bulwarks against winter storms, but as they were neither economical nor expeditious, their use was given up after the sinking of a second crib in the spring of 1859, and every effort was bestowed on getting forward the piling as quickly as possible; to this end great efforts were made to increase the supply of stone, every block thrown in was brought 50 miles in barges from the Toultcha quarries, which were of hard blue limestone "grauwacke," and a quickly pulverizing schist. It was found necessary to forbid altogether the supply of this latter, as it was not able to resist the roll of the sea, but the contractors naturally preferred to work it, as the most easy.

In the course of 1859, the frequent failure of the contractors enabled the commission to withdraw the supply of stone from them, and the quarrying was then carried on under the direction of their own *employees*, with the double advantage of obtaining the stone at a far less price, and in the quantities required. No serious difficulties were encountered from want of stone after the spring of 1860, by which time the working of the quarries was put on a proper footing. In the autumn of 1859, the north pier had been nearly carried to the extent of the project adopted. As no solution of the St. George's question then seemed probable for some time, and the possibility of finishing the second project without prejudice to the permanent works became apparent, it was resolved to continue the works to the extent of the second project, and the north pier was, therefore, continued without doing more to the south pier than to run out a portion of its guage piles, and to protect them with four feet of stone, in the hope that the slack water to the east would silt up, and thus a large outlay on sheet piling and stone would be saved; a hope that was fully realized.

In the spring of 1860, the good effect of the north pier became apparent in an increase of 4 feet to the depth of the channel. By the month of July, that pier was finished to its full length of 4,380 feet; but the want of the south pier to maintain the increased depth became manifest, and this pier was pushed forward with great rapidity. The weather was generally fine, and as the works were under the lee of the north pier, the swell from the more frequent northerly breezes was not felt, and the very great advance of 1,020 feet was made during the months of August and September—of which 830 feet were carried forward in the month of August—so that by the end of the year the effect of the south pier was already perceptible in an increased depth, which in the spring of 1861 reached 16 feet, on a good broad channel from which it has never gone back, though at times it has been as much as 17½ feet.

In the spring of 1859, an Italian vessel, new, and built of oak, was wrecked in mid-channel of the intended direction of the piers. After several fruitless efforts, by native divers, to get a charge below her keel, a diving dress of Heinke's pattern was purchased, which has been found most useful; by means of it, successive charges were lodged under this wreck, during the years 1860–61, and she was thus completely destroyed to a depth of 18 feet.

In the autumn of 1860, it was decided to extend the piers beyond the length projected, and they were completed to the lengths, respectively, of 4,640 feet in the north pier, and 3,000 feet in the south pier, during the spring and summer of 1861. The north pier has been sheeted (both inside and outside) on lines of gauge piles for 40 feet, and the interior filled in with stone. The stone footing, seaward, has been formed of the largest blocks of stone that could be obtained, and every year its base widens by the subsidence of the stone which is constantly thrown in to keep it at the level of the water.

Taking the whole length of the pier, this subsidence is very inconsiderable. After the storms of last winter 1,600 cubic yards of stone sufficed to make good the sinking. At certain points in the length of the north pier, the sea was observed to break with more violence than at others; these portions were, therefore, strengthened by enclosing a solid block of 30 or 40 feet of pier with sheet piling and filling it in with stone. At certain intervals, too, the space between the inner and outer piles was sheeted to check the enfilading roll of the heavy seas as they curled round the pier-head, and the displacement of the inner pile of stones was thus prevented.

At the head of the north pier a small timber light-house was built on piles driven through, and forming part of the "musoir," in which a light is kept during all but the winter months, when the pier becomes a solid mass of ice, which cuts off the light-house from assured communication.

The immense weight of ice thus heaped upon the pier has, up to the present time, never seriously damaged it. The head of the south pier is formed of a large crib which presents a solid mass on which the waves break harmlessly; it is, of course, well protected with stone.

The mode of construction and the changes introduced from time to time both in it, and in the extent of the piers, having been now explained, a general idea will be given of their direction, and of the gradual growth of the channel produced by them.

The north pier is a continuation of the left bank of the river. It is 4,640 feet in length, and is carried out to what was the 16-foot line before the works were begun in 1858. The pier runs east for 2,250 feet; thence it curves slightly to the north for 1,550 feet, on a radius of 6,000 feet; and the remaining 840 feet of its length runs E. by N. ½ N.

The south pier springs from the lip, forming the right bank of the river, at a point due south of the 1,900th foot of the north pier, which it approaches on a curve of 2,400 feet radius, for 2,400 feet, when it arrives at a point 600 feet from the north pier, to which it then runs parallel for 600 feet, leaving the latter to project 650 feet beyond it.

By the autumn of 1859, the north pier had attained a length of 2,700 feet protected by stone, the timber work being some 300 feet further out.

The south pier had, by that time, been carried out only in frame work without sheet piling or stone for 1,300 feet, and, therefore, exercised no effect on the current. At this stage of the works, the theory of an Austrian engineer, Mr. Wex, that only one pier was needed to remove the bar, seemed about to receive confirmation; for, in the spring of 1860, there was a narrow channel of 15 feet, and a good broad channel of 14 feet deep.

The spring and summer floods of 1860, however, quickly dispelled any illusion on this subject; for although the north pier had become 4,500 feet long by the beginning of August in that year, and the south pier, in skeleton, had reached the deep water, the old bar had speedily reformed in its old position, and there was a channel of barely 8½ feet. The object of carrying out the north pier first had been to gain shelter for the works on the south pier against the swell raised by the prevailing wind. As the north pier was now nearly at its full length it was decided to fill in and extend the south pier energetically; and by the end of 1860, this had been so well done that the timber frame-work had a length of 2,700 feet, of which 2,350 feet were solid, with the exception of 450 feet near the root, left open as above stated for the escape of flood waters.

The effect of the south pier became apparent as soon as it reached the channel; at the end of September, 1860, when it began to take a direction parallel to the north pier, the depth had increased to 9½ feet, in November to 11½ feet, and by the end of the year to 13 feet.

The early spring floods, which were in 1861 of unusual violence, gave a channel of 16 feet, which reached 17½ feet when the piers attained completion in the month of August, 1861.

Piling is used outside both the inner and outer gauge piles; these are oak piles which have been driven since

the completion of the piers to increase their strength and durability, and to prevent any ill effects that might arise from the gauge piles of pine perishing.

The advantages possessed by these works may be stated as:—

1. Their fitness for the object sought, as proved by their success.

2. The rapidity with which they can be extended to remove any serious shallowing of the channel.

3. Their cheapness; their section having been found to be amply sufficient to resist, not only the shocks of the sea, but very heavy collisions with vessels which have been driven upon them, and yet their first cost has only been £10 a foot forward in 16 feet of water.

It may be interesting to those who have accompanied the author thus far in this subject, to know what works have been proposed for the permanent improvement of this fine river.

The narrow and shoal channel of the Sulina above the lower 18 miles of its course, and the broad deep channel of the St. George throughout its whole length, together with the greater depth and more rapid slope of the sea bottom in front of its embouchure, have not allowed engineers and sailors to hesitate between the two rivers; they have declared unanimously in favor of the St. George, which would long ago have been opened but for the political considerations which were involved in it at first, and which, always resting professedly on engineering and financial reasons, have of late been strengthened by a division of opinion upon the system of works to be carried out.

The Commission of Engineers appointed to examine the technical question, whilst entirely in favor of opening the St. George, pronounced in favor of a lateral canal, leading from a point above its mouth into the sea to the north of the embouchure.

The opinion of those acquainted with the localities founded upon the examples, cited in the first part of this paper, is entirely opposed to the formation of the canal, and a long suspension of the permanent works has, consequently, taken place. It is probable, however, that a decision will before long be arrived at upon this subject.

ADDENDA.

GALATZ, *June 23, 1864.*

With reference to the concluding remarks on the effect of piers at the Sulina entry in the former part of the preceding paper, the author is desirous to give the experience gained during the last nine months, which is instructive.

In his paper (concluded and revised in September, 1863), he mentioned the absence of floods in 1863, and the consequent feebleness of the current, which had given rise to the formation of a bank in a position where it was not expected, but whence it would be easily removed by the first floods.

The correctness of this anticipation has been proved this spring. As 1863 advanced, the river became lower and lower, the current ever feebler, till it barely reached a quarter of a knot per hour. The bank between the pier heads grew up to within 14 feet of the zero level, except in a very narrow channel; but to sea-ward of the north pier, there was no filling up. In March of this year the river began to rise, and the current to increase.

The effect on the entry was immediate, and in less than a month there was again a navigable channel of 15 feet deep, which by the first week in May was increased to 15½ on a width of 150 feet, and the shoal of 13 feet, on a length of 700 feet, reduced to one of 14 feet on a length of 150 feet.

This large slice of shoal was not taken off to be deposited again in front of the piers, for the 15 and 18 feet lines are still where they were. The surveys of 15th of February, 1st April, and 6th May show the improvement due to the current, and how little deposit has formed outside, although the waters have for the last two months been thick with alluvial matter.

The floods, although considerable, have not exceeded an average height, and therefore the current has rarely exceeded, and not often reached, two knots an hour at the mouth; otherwise a greater depth would doubtless have been obtained.

The experience of the last three years has shown, that any bank formed outside is speedily broken down by the waves in the frequent gales from the N. E., and their substance carried away southwards by the littoral current; whereas, a shoal arising from the feebleness of the current at the point where the parallelism of the piers ceases, being under shelter of the north pier, and therefore not exposed to the break of the sea and the littoral current from the north, does not get removed till a flood comes down.

This being the case, Sir Charles Hartley has suggested that it would be better to prolong the south pier so as to push out any such bank beyond the shelter of the north pier, that it may be attacked and broken up by the breakers in northerly gales.

Against such a prolongation are two considerations. The first is, that the bank being left to form beyond the influence of the piers might spread over too wide an area, to the possible blocking up of the entry. The second is, that even should the bank form only in a continuation of the line of its present position, vessels entering the port with a northerly wind would have the bank under their lee, without the protection they now enjoy from the north pier, which prevents their being set on to the bank. This question will probably be set at rest by experiment, by prolonging the south pier. Should its co-extension with the north pier be found to offer more hindrances than advantages to the navigation, the north pier can be extended until it again projects beyond that of the south.

This experiment can be tried at a moderate cost, and, as it can but result in a general prolongation of the piers into deeper water, must lead to a decided improvement of the entry—with the additional advantage of showing which is the best relative extension to establish for the two piers.

LONDON STREET SWEEPING.

In a former letter some account was given of the vast subterranean works by which London is drained and purified, and it now remains to speak of the operations above ground, the cleansing of the immense area occupied by the modern Babylon. Some estimate of the extensive nature of these operations may be formed when we reflect that the streets of London, if placed in one line, would form an avenue of 7,000 miles in length. In the daily cleansing of the streets about 14,000 men find employment, which gives an average of two to the mile, but the number fluctuates according to the season. In the service of this army are 6,000 horses and 2,400 carts.

The City Commissioners of Sewers, upon whom devolves the task of keeping the streets clean, do all their own work, and make the most, commercially, of the garbage with which they have to deal. The "city" has its own engineer-in-chief, at a salary of £2,000 per annum, and he has his staff of assistants, superintendents and men for the carrying out of every department of street government. One corps of laborers is told off for the sweeping of the streets; another for their washing; a third for the collection of the refuse; a fourth for the carting away of the same, and a special body is employed in attending to the public street conveniences. The payroll of the street cleaners amounts to £28,000 annually for the "city" alone, which would give a staff of about 560 men. These are divided into scavengers, carters, street orderlies, dust sifters, mud puddlers, etc.

THE NIGHT BRIGADE.

The work of street government goes on day and night, but the actual sweeping does not commence until eight o'clock in the evening. From that hour until daybreak files of men occupy the street, which are then hourly becoming more silent and empty as the night wears on, the laborers themselves moving their immense brooms with automaton-like regularity, and with an air of melancholy which befits the time and is in keeping with the dreary gloom around them. One wonders what becomes of these night birds in the day time. In what "rookery" do they pass the hours of light and sunshine? Do they ever talk or hold up their heads?—for one of the results of their occupation is a confirmed stoop of the shoulders. Whole regiments of them, formed in line, may be seen during the night performing their tasks and looking like brigades of hunchbacks. Most of them are old men, or at least look old, for one and all have that strange, wizened, dried-up look which defies any guess at real age. Some of them have taken to the business from downright affection, and their histories would form a strange and entertaining chapter of human biography. The story of one of them at least is known. The hero of it is now an inhabitant of one of the workhouses. Twenty years ago he drove his carriage and pair, and carried on a business which brought him in £10,000 a year. He lived luxuriously, kept open house, and took an active part in the local government of his district. Misfortune came, and in a single week he found himself an absolute pauper, and finally a street cleaner, sweeping the very pavement from which his own carriage had many a time stirred the dust. Some of the night workers do duty during the day as

"SANDWICH MEN,"

a slang term for the miserable creatures who perambulate the streets, carrying boards slung over their shoulders, before and behind, forming a kind of wooden chesable, whereon are pasted advertisements. Poor, broken-down men, with abject mien and gait, these walking advertisements traverse the muddy streets under their degrading burden for the vast sum of one shilling a day. When night comes they take to their brooms, and in the early hours of the morning may be found sleeping on the wooden settles of the common lodging houses.

THE CARTERS.

Following the army of sweepers comes the carts, each attended by two strong looking men, clad in dingy smock frocks and immense "sou'wester" hats, and bearing large shovels with which they scoop up the mud, dirt and other refuse and pitch it into the carts. Up in the narrow streets of the densely populated neighborhood a midnight stroll will reveal huge pools and heaps of offensive matter collected before the entrances of courts and alleys which have been brought by the night soil men from the backs of the poorer dwellings and await the arrival of the carts. Every ounce of the refuse is conveyed to depots, that is to say, large open spaces where the liquid matter is thrown into reservoirs made of mud, and is eventually transferred to barges on the river.

DISPOSITION OF THE REFUSE.

The fluid refuse having been shipped is conveyed towards the mouth of the Thames, where it is discharged into the water. The solid matter is differently dealt with. In the depot yards women and girls are employed in sifting the ashes and rags which are used for bottoms of new streets and other purposes. The cinders are used for burning bricks at the limekilns and the residue as cement or manure. The women employed in this dirty work receive generally $1.25 a week, and the maximum received by the men is about $6, while the barge owners get sixty cents per cubic yard for conveying the liquid refuse down the river.

THE MUD BARGES.

The crews of these barges are an extraordinary class of beings. Mr. Silas Wegg, "to whom all print was open," knew them and their ways, but they are now hardly as lively a race as when the Golden Dustman dealt in their wares. They spend their life on board the barges, men and women together, and, as a necessary result, children often see daylight, or, more frequently, a London fog, for the first time in their filthy little holes called cabins. The language of this floating population is peculiar. It is a *patois* of the rough sailor's style of blasphemy with a mixture of the costermonger—Romany jargon. "They do swear most awful," these uncouth mariners, and have an unconquerable aversion to the white tie of the evangelizer and the uniform of the river police. All the efforts of benevolence, committees of lords and gentlemen and societies of ministers to christianize these unruly nomads have failed. A gentle lady, who has a decided talent for evangelization, has been known to visit the bargemen in their abominable haunts, but even she did not make the slightest impression. They enliven the monotony of the voyages down the stream by puddling the mud and examining the cargo with all the scrutinizing, covetous instinct of the Parisian *chiffonnier*, in search of such valuables as may have escaped the operators at the depot. Whenever they "make a haul," which is not an unfrequent occurrence, they signalize their good luck by a drunken orgy in the public house nearest to their moorings by the river side. It is said that many an assassin's secret has been hidden in

the hold of a Thames mud-barge. The police suppose that many of the dead bodies found in the river, especially those who bear upon them the marks of foul play, have been thrown overboard from the barges. The bargemen, they say, may receive a "parcel," with instructions to discharge it with the cargo or to drop it quietly to the bottom on their way down with the tide.

THE CROSSING SWEEPER.

At what precise date in the history of London this knight of the broom made his appearance is not on record, but to judge from what London was and what it still is, his services must have been indispensable at a very early period, and, indeed, were far more necessary in the London of the past than in that of our own days, as will be evident from a quotation from Knight's work on the metropolis.

THE LONDON STREETS IN 1720.

"The middle of a paved street," he says, "was generally occupied with the channel, and the sides of the carriage way was full of absolute holes, where the rickety coach was often stuck as in a quagmire. The only road to the houses of Parliament before 1750 was through King street and Union street, "which were in so miserable a state that fagots were thrown into the ruts on the days on which the king went to Parliament, to render the passage of the state coach more easy." The present St. Margaret's street was formed out of a thoroughfare known as Saint Margaret's lane, but which was so narrow that "pales were obliged to be placed, four feet high, between the foot path and the coach road, to preserve the passengers from injury and from being covered with the mud which was splashed on all sides in abundance." The pales preserved the passengers more effectually than the posts of other thoroughfares. These posts, in the principal avenues, constituted the only distinction between the footway and carriageway; for the space within the posts was as uneven as the space without. This inner space was sometimes so narrow that only one person could pass at a time, and hence those contests for the wall that filled the streets with vociferations of anger and the din of assaulting sticks and sometimes the clash of naked steel. Dr. Johnson describes how these quarrels were common when he first came to London, and how at length things were better ordered. But the change must in great part be imputed to the gradual improvement of the streets. In Gay's time there was no safety but within the posts:—

> Though expedition bids, yet never stray
> Where no ranged posts defend the rugged way;
> Here laden carts with thundering wagons meet,
> Wheels clash with wheels and bar the narrow street.

In wet and gusty weather the unhappy walker heard the crazy signs swinging over his head, as Gulliver describes the Red Lion of Brentford. The spouts of every house were streaming at his feet or drenching his laced hat and powdered wig with unpitying torrents. At every step some bulk or shop projection narrowed the narrow road and drove him against the coach wheels. The chair-men, if there was room to pass, occupied all the space between the wall and the posts. The "hooded maid" came sometimes gingerly along, with pattens and umbrella (then exclusively used by women), and of courtesy he must yield the wall. The small coal man, the sweep and the barber took the wall, in assertion of their clothes spoiling prerogative, and the bully thrust him or was himself thrust "to the muddy kennel's side." But at whatever period the crossing sweeper first took his place as one of the institutions of London it is certain that he has ever been an interesting subject of study to novelists and essayists and occupies a distinct space in English literature. His was always a prosperous trade, no doubt, in such a muddy city as London; although not many, like Charles Lever's hero, could have left their crossings to become diplomatists and dine with the Prince Regent. In the days of the Regency the crossing sweepers had a trade union of their own, with rules unwritten, but rigid. Not more than twenty years ago there existed in one of the back slums of Oxford street a tavern where the West End sweepers used to take their ease in their inn. Here was kept a record of vacant crossings and a list of such members of the fraternity as desired to retire from business and sell their interest. There is a story of one old fellow, with a wooden leg, who waited for years before he would retire. He owned a crossing in Pall Mall for which he wanted $1,000. He had established the crossing himself, in the days when clean swept paths across the streets were more wanted than they are now, and had swept it for twenty-five years. It was worth $5 a day to him on an average; the "nobs" knew him, he said. A certain noble lord gave him a half-crown every day for keeping the mud off of his patent leather boots, and a duchess, he averred used to smile on him so blandly whenever she crossed that the old man almost forgot to hold out his trembling hand for the coin, which on occasions was a five shilling piece. He sold his crossing at last, and for years after frequented the sweepers rendezvous, where he generously assisted his less fortunate brethren of the broom.

STREET ORDERLIES.

Any visitor who for the first time walks the streets of London will be surprised and amused by the legion of boys, distinguished by a brass plate on their caps, who rush about the carriage ways, sometimes on all fours, and recklessly precipitate themselves in front of rapidly advancing hansoms, omnibuses or drays, with an apparent determination to commit suicide. Where certain death seems inevitable, there will the "street orderly" be found. Where two vehicles are swiftly approaching each other in a narrow street and there is barely room for them to pass, then is the moment for him to rush forth between them. If the traffic be dull and the street half empty of vehicles, you may look for him in vain, but amid the clatter of a hundred hoofs, the rattle of many wheels, there may you see him plying his brush and shovel. For his business is to collect the horse droppings in the very heat of the traffic. The wonderful agility and coolness of these boys is acquired by a course of training under the superintendents of the streets. The lad who aspires to the dangerous vocation of a "street orderly" must not be less than twelve years of age, and he cannot continue at it after he is sixteen. There are 140 of these boys employed by the authorities at wages varying from $1.50 to 2.25 per week, according to age and length of service. For ten hours of each day do they rush about the streets and dodge for their lives. Having filled their shovels with the manure they empty it into iron bins erected at intervals along the sidewalks and it is then removed in carts and sold. The manure is worth at the lowest value $5 per ton, and he must be a lazy orderly indeed who, in a crowded thoroughfare, does not collect a ton in a week. The average, in fact, is about a ton and a quarter. The boys are for the most part children of the men already in the employ of the Commissioners and are destined as a rule to spend their lives in the noble avocation of street cleaning. It is an amusing fact, that the manure bins are so frequently mistaken at night time for pillar posts that the carters are instructed always to carefully examine their unpleasant contents, and not a morning passes without a considerable number of letters—business letters, love letters, letters containing money and valuables—being forwarded to the Post Office as a result of the examination.

STREET FISHERS.

The street fishers, inasmuch as they have a hand in the work of street cleaning, deserve a passing notice This industrious class of the motley population of the great city is composed chiefly of women. Now that the work of general cleansing is undertaken by the public bodies, the female street fisher is to be found in courts and alleys, in the back slums and the streets leading to the river. She is not young. She is not beautiful. She is either a sturdy, middle-aged Amazon, or a decrepit old hag. Clothed in a mass of shapeless rags, occasionally enveloped in a man's overcoat, a tattered bonnet on her unkempt head, her stockingless feet thrust in a pair of rough shoes, she may be seen, stick in hand, basket on back, setting forth in the early morning on her rounds. From the dust heaps she extracts rags, bones, broken bottles—anything that is of the slightest value. She follows the coal carts and picks up the droppings, and watches the great wagons laden with vegetables for the same purpose. Round the warehouses and factories she prowls, gathering up any stray fragments of raw material which may lay about the gateways. A few grains of Indian corn—a little oatmeal burst from the package—will furnish the poor creature with a meal for the day. At night time she betakes herself to some back yard or the underground kitchen of her lodging house, where she sorts her treasures into lots, disposes of them for a trifle to the dealer, who in turn takes them to the manufacturers. All the finds of the street fisher are not so marketable, for now and then under a dirt heap a dead baby is brought to light. A certain class of street fishers devotes itself to the collection of dead animals. It is computed that every year the London streets and alleys yield a harvest of 500,000 dead dogs and cats. Their skins and entrails are utilized for various articles, such as gloves, fur-caps and fiddlestrings, while the flesh—but the horrible thought of sausages urges us away from pursuing the subject further! When, at last, after years of this hard, unsavory life, the street fisher dies in the Workhouse, she is bundled into a shell and buried with little more ceremony than if she was one of the dogs or cats by which she made her living.

THE CONTRACT SYSTEM.

The contracts made by the vestries for the cleansing of the streets are generally for a term of years. Every department of the work is contracted for, including the sweeping, watering and carting, and in most cases the contractor receives the refuse to dispose of as he chooses. In this way the Buffinses of old and of to-day amass fortunes before they have mastered the alphabet. They do what the vestries, one would think, might do for themselves—carefully sort and select the refuse of the streets and turn it to good account. The smallest piece of waste paper found among the debris has for them its commercial value, and the rich manure which is manufactured out of street sweepings yields them a large profit. But even without these "perquisites" the prices at which they obtain their contracts would enable them to acquire moderate fortunes within a short time. The contractors have really a vested interest in and a monopoly of the work of the local bodies. Nominally, of course, the contracts are open to competition, but the tendering is probably a mere pretence. The contractors are of a lower class than even the vestrymen, and as their business is a particularly repulsive one, which cannot be properly conducted without close personal attention to all its details, they have but a small competition to overcome. They generally begin in a small way—often on money borrowed from some of the vestrymen (at heavy interest, no doubt), and as the less experienced or less intelligent men fail for want of means in performing the small contracts the more successful man buys them out. In this way one contractor has been known to acquire contracts for nearly the whole of one side of the river Thames, within the metropolitan area. An Irishman, and coming to London with nothing but his rich brogue and mother wit for capital, he now lives in a magnificent suburban villa surrounded by ornamental grounds, keeps carriages and horses, but yet visits daily his dirt depots and personally superintends all the details of his immense business. He will die a millionaire, and the name of Daniel Redman—for so is the Golden Dustman called— will be remembered as that of the largest and wealthiest employer of street labor on this side of the Atlantic. If a company with adequate capital were to undertake the whole cleansing of the vast Augean stable by contract the work would yield a good profit, and at little more than half the present cost, but the present practice is so much a part of the system that there is not much chance of any change.—*N. Y. Herald.*

Accident to a Caisson at the Willems Bridge, over the River Nieuwe Maas at Rotterdam. By D. A. WITTOP KONING.*

An accident of a serious nature occurred during the sinking of the caisson for that pier of the railway bridge which is close to the quay wall of the town. Excavations had to be made in the caisson under compressed air, supplied by two force-pumps on a staging erected on piles round the caisson. The latter was of oblong shape, 84 feet 7 inches long by 24 feet 6 inches wide, with semicircular ends. It consisted of two chambers; the lower one was 11 feet 9 inches high, with sides of wrought iron lined with brickwork, with a roof of concrete and brickwork carried by iron beams; the upper chamber, fixed upon the roof of the former, was constructed of wrought-iron segments, bolted together, and stiffened inside by angle irons and a strong lining of brickwork. Four shafts connected the chambers; two for materials, and two for

*Abstracts of Papers in Foreign Transactions and Periodicals. The Institution of Civil Engineers, London.

the workmen. The caisson was built ashore upon a slip, and was floated out to the site between two pontoons, air being pumped in to keep it floating. Having arrived over its position, the staging was closed around it, and bricklayers were set to work to carry up the lining; the pier thus gaining weight, sank gradually.

Unfortunately, however, the cutting edge at the north side struck the piles of the surrounding staging and the caisson, being held up at one corner, went off the level. Air was pumped in again, but, though the rising tide lifted it off the piles, it struck some boulders which had been thrown around the caisson to prevent scour. The south side, now clear of the piles, continued sinking, and, in spite of all efforts, could not be stopped until the pier was leaning at an angle of 45°, having considerably damaged the surrounding staging in its course.

The contractor saw no other way of bringing the caisson back into its place, except by tackles fastened to anchorage on shore, which would have been no easy task, owing to its great weight and unfavorable position. The tackles would have required chains to be passed round the caisson, and it was feared that the latter would not be strong enough to withstand the pressure, and would either have parted from the lower chamber or collapsed. It would have necessitated on shore strong and expensive anchorage in the soft strata behind the quay wall, and it was calculated that a force of 1,000 tons, by means of fifty cables, each bearing a strain of 20 tons, would have to be applied.

Among the numerous proposals, that of the author was selected. He advised the building of a cofferdam inside the caisson, which, when pumped dry, would, as he demonstrated, yield a floating power three times greater than required. Amongst other advantages, his scheme obviated all danger of bringing the pier up suddenly. The lifting force had its greatest leverage at the moment when the greatest force was required, namely, in the beginning, diminishing gradually until the pier was in a vertical position, and its centre of gravity in the same vertical line with the centre of flotation.

The dam was commenced on June 15th, 1875, and consisted of double-grooved sheet piling, 39 feet long, 10 inches thick. At first each pile was set separately, by a diver, in a sext cut for it in the brickwork. As the work progressed, it was found advantageous to set them in sets of four at a time. They were pressed together by a windlass, and the joints were caulked with oakum. In spite of this precaution, much trouble was encountered through leakage. After spreading a tarpaulin over the outside of the dam, two centrifugal pumps, driven by two portable engines, were started on September 24th, the diameter of one being 7 inches, that of the other 4¾ inches. When a difference of 3.15 inches between water-levels was observed, the pumps had to be stopped and the leaks repaired. It appeared that the dam had come away from the ironwork at the east end, and a considerable leak had to be stopped with old sacks and clay. Pumping was recommenced on October 7th with five pumps and five engines. A difference of 4 feet 4 inches was attained, whereby the first definite rising of 2.36 inches was noted. By this mode of working, this angle was reduced from 45° to 22° 25′ on October 28th, when the greatest difference between water-levels, 16¼ feet was noted. It was now decided to apply mechanical power by chains and crab-winches. On November 1st, when the pier stood at an an angle of 16° 45′, the west cable parted, the links being 0.98 inch thick. It was made good, and work resumed with a strong flood tide, when the last cable, with links 1.34 inch thick, gave way. Accordingly it was determined to have recourse to compressed air in the bell, which was forced in on November 3rd. This was followed by an immediate rise of the pier, and improvement of the angle. The inclemency of the season now put a stop to further work. In the meanwhile everything was prepared to start with a fourth method, consisting in the application of screwjacks applied to the south side of the caisson, arrangements being made to prevent the north side from rising, so as to cause the caisson to move bodily to the southward. This effect was still further increased by casting more rubble stone on the north side. During this work, 2,000 tons of stone were tipped on the north, but none on the south. Bad weather continuing, the travellers were erected; the staging was finished and protected against ice-drift, and the iron skin of the caisson was carried up to withstand the extraordinary height of the tides. On January 26th, 1876, it was first possible to start screwing up, the clay having been removed from inside the southside to lessen the resistance; and on February 9th the latter rose 19.68 inches, reducing the angle to 3° 50′. The lifting was then stopped; the screws were wedged up, and the air let off. During this period, the sinking of the pier to its ultimate depth, and the building up of the brickwork slowly advanced. By distributing the brickwork, and by careful excavation, the pier was brought quite upright. The work was greatly impeded at this time by high tides. On May 24th—one year and three weeks after the commencement of operations—the pier reached its ultimate depth.

In its fall it had slid from its proper position to the northward, so that at the east end it was 6.9 feet, and at the west end 8.36 feet from its intended place. By tipping a bank of rubble on the north side, the displacement was reduced at the end of the second period to 5½ feet of the east end, and 7½ feet at the west end. Afterwards this was further reduced to 10.68 inches and 4 feet 5 inches at the respective ends, so that no alteration of the superstructure was necessary.

CORRESPONDENCE.

RICHMOND, VA., *June 4th, 1877.*

Editor ENGINEERING NEWS:

SIR.—Can you put this problem before your readers in such a form as to elicit a solution, or can you refer me to any text book containing the information? I know of none.

In a railway culvert the cross section of which is a parallellogram surmounted by a semicircle, what proportion should exist between the sides of the parallellogram?

Very respectfully yours,

SUBSCRIBER.

PORT EADS, LA., *May 29, 1877.*

Editor ENGINEERING NEWS:

SIR.—The scour at the upper portion of the jetties is progressing very favorably and the deep water contours are steadily advancing seawards. The greatest channel depth at present is at a point 4,900 feet below the Eastern Landsend, or nearly half way down toward the seaends of the jetties. The depth, which is 74½ feet, is at the same spot where the coast survey map of 1875 shows 13 feet. The volume of sand removed from within the jetties between the 2d of March and 26th of May of the present year, amounts to 467,000 cubic yds. Taking into consideration that scour can only be effected by expending velocity on friction, it is evident, that in order to accomplish the removal of such a waste mass of material, the bearing capacity of the volume passing through the jetties had to be taxed very considerably, adding, in this instance, for the time being, in the average not less than 13 per cent. to the already enormous amount of sediment which the Pass carries in suspension. Considering, furthermore, the fact that this addition is being applied at a moment when the volume is ready to enter the Gulf, you will find it doubly surprising, that no trace of a deposit can be found beyond the crest of the bar. But examinations of the Gulf bottom directly in front of the jetties, made this mouth give evidence that the depth over the entire area investigated (51.7 acres), is now 4.99 feet greater in the average, than it was in the same locality in May, 1875. A more convincing proof for the success of the improvement can hardly be found. Very truly yours,

MAX E. SCHMIDT.

OGDENSBURG, N. Y., *May 30, 1877.*

Editor ENGINEERING NEWS:

SIR.—Your paper last year contained some extracts from my report on the Construction of the Kansas City Water Works.

After their completion so far as to enable them to meet the requirements of the contract for their construction and operation, the city refused to accept their services and the controversy finally passed into litigation. The city procured the services of two engineers from St. Louis, whose report, carefully kept from the Water Company for use in the then pending trial, has first been made public through the columns of your paper, (April 21, 1877).

These gentlemen are well known to be opposed to the Holly system of water supply. One of them had made an estimate for reservoir works at Kansas City previous to the inception of the present works, his estimate footing up something over a million, and a perfectly fair report could hardly be expected from them, especially as made for the express purpose of doing the works all the injury possible. I was not, however, prepared for their sweeping condemnation, and as the controversy between the city and company has been amicably adjusted by a compromise of the original contract, satisfactory to both parties, the only effect the paper could have at the date of its publication is on my standing as an engineer.

I therefore wish the privilege of a reply, this being the first leisure I have had since its publication.

Their first attack is on the quality of the water supply; this, by the terms of the contract, is a question for chemists, not for engineers; but they see fit to infer fraud on the part of the company in sending samples of water for analysis different from those obtained at the source of supply.

I was present when these samples were taken by the water commissioners from the sources named in the pamphlet and know them to be as represented.

Their next is on the quality of material and workmanship: first item, receiving cribs at the Kansas river. These were built of the best quality of southern pine; that portion above low water will need occasional repairs when the timber fails from age; that they are efficient is undeniable, and the cost of maintenance will be less than fifty dollars per year.

It is not to be expected that a private corporation will do as expensive a class of work as that which has made the five million water-work's debt of St. Louis, but as they are to own and operate these works for twenty years they would not naturally wish to do merely temporary work.

The receiving well next takes attention; the lower part of this, of boiler iron painted thoroughly before sinking, is claimed to be temporary, and liable to rust out. I believe this will last longer than the present capacity will be sufficient, but it is fully accessible and can be lined with brick at any time if desired, at a cost of about two hundred dollars.

The reservoirs come next; to describe the construction of these in detail would occupy too much space. They were built upon plans based on the authority of twenty-five years successful use, and were submitted to and had the approval of practical and able engineers. The tops of the banks were originally ten feet wide, inner and outer slopes 1½ to 1; the tops have since been rounded off; they were intended to have been grassed outside, but this has not been done as yet. The brick facing in the lower reservoir is set in cement, and the limestone facing of the inner slope of the upper reservoir is an edge paving, filled in next the earth with small stone—the character of the earth is such that it will hold water permanently when simply filled in with ordinary embankment. The most of the upper reservoir is excavation; where it approaches the crest of the hill it has an outer retaining wall, the base of which is equal in breadth to its height; at this, the narrowest part, the embankment including the retaining wall is 70 feet thick at the base and 20 feet at the flow line. At present they are of ample capacity for all requirements and land is provided for their extension when necessary; the concrete of the lower reservoir and the tops of both embankments (the surface of which is in the report called "plastering"), was injured by frost, and cement was provided for its renewal last year; the work was, however, delayed till the present season by fear of frost.

The placing of all the machinery in one building was not my work, and I think the company believe as I did then that two pumping stations would have been better. The present arrangement, however, is objectionable not on account of lack of efficiency, but from the complication of machinery necessary to obtain the required results.

Ability to perform tests of throwing streams for fire service; here they propose to use an outside line of pipe which at the request of the water commissioners was changed from its direct connection with the system of mains as originally planned, and carried around a circuit of about a mile, to serve an otherwise isolated locality, on which it is not probable that more than two or three streams would ever be required at one time. Small and long as this line is, however, 12 one-inch streams have been thrown from it at one time to heights of from 100 to 140 feet. A trial of streams in lower town, as indicated, would very soon convince any one desiring it that there *was* a communication with the machinery; this is usually kept closed to relieve lower town of excessive pressure; the reservoir pressure being sufficient for all requirements.

Estimates of cost: On this subject I am not at liberty to speak definitely, the company not having made their expenditures public. It is evident, however, that their estimates are based on a like view with the rest of their report. For instance, the building and well which cost some $43,000 by day labor is estimated at $20,800, and the machinery weighing some 200 tons, and of a class approaching locomotive work in cost, is estimated at $50,000. G. W. PEARSONS.

CHARLESTOWN, MASS., *May 28, 1877*

Editor ENGINEERING NEWS:

SIR—In reading over the excellent discussion of the theory of the braced arch given in Prof. Du Bois' "Graphical Statics" (John Wiley & Son's Edition), I have found the following corrections necessary, which it seems desirable to bring before the readers of the work at once. At the request of Prof. Du Bois I therefore transmit them to you, hoping you will give them a place in your journal for the benefit of those who may have occasion to use the article referred to.

I will first state that the errors here given affect mainly but a single chapter in a supplement, and not the general theory, which is correct, or the main portion of the *text* of the braced arch, in which, on the contrary, with a single slight exception given below, no essential errors have been found in a careful and thorough perusal.

I would also state that the development of the theory of the braced arch given in this book is one of the best and most satisfactory to be found in the English language; and from what I have read of the work, I regard it as one of the best books relating to the engineering profession, and value it highly.

The corrections are the following:

On page 268 the last line should be $M = Hy + M$.
x

On page 286, in the last formula, for the term "$2\,(1+k)\,\alpha\cos.^2\alpha$," substitute $2\,(1+\frac{k}{2})+\cos.^2\alpha$.

On page 296, last line, for "large" read "small."

On page 305, equation (72) should be

$$H = \frac{P\,(a^2 - 2az \pm z^2)}{4h},$$

in which the sign $\pm$ is to be used according as z is essentially positive or negative.

On pages 307 and 308 erase from "(*c*) Moment at unloaded end" to "34. Circular arch," and substitute the following: For the moment at the crown we have from (37), Art. 14, for a single load

$$M_0 = -\frac{1}{32}\frac{P\,(3a^4 \mp 16a^3 z + 18a^2 z^2 - 5z^4)}{a^3},$$

in which, again, the sign $\mp$ is to be used according as P is to the left or right of the crown, or z positive or negative.

Taking the first expression and substituting for P, $-pdz$ and integrating between the limits a and z, we have for the moment at the crown when the load, coming on at the left, does not extend beyond the crown:

$$M_0 = \frac{p}{32a^3}[z\,(3a+2)\,(a-z)^3]$$

This expression is zero for $z = 0$; and hence, when the load extends from the left abutment beyond the crown, we shall obtain the moment at the crown by substituting for P, $-pdz$ in the second of the expressions given above for M_0 in the case of a single load, viz:

$$M_0 = -\frac{1}{32}\frac{P}{a^3}(3a^4 + 16a^3 z + a^2 z^2 - 5z^4),$$

and integrating between the limits 0 and z; — which gives

$$M_0 = \frac{p}{32a^3}\,z\,(3a - z)\,(a+z)^3.$$

Hence, we have the general formula

$$M_0 = \frac{p}{32a^3}\,z\,(3a \pm z)\,(a \pm z)^3,$$

in which the upper row of signs is to be used when z is positive, the lower row when z is negative,—the sign of z being implied in it.

M_0 has its maximum positive and negative values for $z = \pm a\,(-1+\sqrt{\frac{8}{9}}) = \pm 0.264911\ a$, or nearly $\frac{1}{4}\ a$.

The moment at the unloaded end is given by the formula

$$M_2 = \frac{-p\,(a^2 - z^2)^2\,(a-z)}{16a^2},$$

in which z may be be either positive or negative.

This moment is always negative, and has its greatest value for $z = -\frac{1}{3}\ a$.

The values of V_0, H, M_0 and M_2 are given in the following table:

z	V_0	H	M_0	M_2
1.0	0	0	0.000	0
0.9	0.00024	0.000579	+0.0001097	−0.0002256
0.8	0.0019	0.00428	+0.000760	−0.00162

−0.3	0.37074	0.38242	−0.010612	−0.0672831
−0.4	0.4459	0.41846	−0.009180	−0.06174
−0.5	0.52734	0.44824	−0.006836	−0.0527344
−0.6	0.6144	0.47104	−0.004320	−0.04096
−0.7	0.70624	0.48669	−0.002185	−0.0276356
−0.8	0.8019	0.49572	−0.000760	−0.014580
−0.9	0.90024	0.49942	−0.0001097	−0.0042869
−1.0	1.0000	0.5000	0	− 0
a	*pa*	$\frac{pa^2}{h}$	pa^2	pa^2

On page 310, line 2, read

$$H = \frac{pr}{24\left[(1+k)\frac{\pi^2}{4} - 2\right]}\Big\{[\pi - 6\beta - 18\sin\beta\cos\beta - 12\beta\sin^2\beta + 6\pi\sin\beta + 2\pi\sin^3\beta + k(-5\pi - 12\beta\sin^2\beta + 6\beta - 6\sin\beta\cos\beta + 6\pi\sin\beta + 2\pi\sin^3\beta)]$$

For line 5, page 310, read

$$H = \frac{pr\,(\pi - 6\pi k}{12\left[(1+k)\frac{\pi^2}{4} - 2\right]}$$

Line 6, page 310, for "unloaded end" read "crown."

Line 8, same page for M read M_0.

Line 12 " " M read M_0.

Lines 15 and 16, same page, should read thus:

For a uniform load over the whole span the moment at the crown would be twice as great as for a load on half the span, for which β would be equal to 0, and hence for a full load

$$M_0 = \tfrac{1}{2}\,H\,r\left(2 - \cos\alpha - \frac{\alpha}{\sin\alpha}\right) - \frac{pa^2}{6} \quad . \quad . \quad . \quad (83)$$

As before stated, this communication is made at the suggestion of Prof. Du Bois for the benefit of those possessing the book.

Yours very truly,

C. W. KETTELL.

BOOK NOTICE.

Strength and Determination of the Dimensions of Structures of Iron and Steel, etc. By Dr. Ph. J. J. Weyrauch. Translated by Prof. A. J. DuBois. New York: Wiley & Sons.

Strength and Calculations of Dimensions of Iron and Steel Constructions, with Reference to the latest Experiments. Translated from the German of J. J. Weyrauch, Ph. D., Polytechnic School of Stuttgart. With four folding plates. New York: D. Van Nostrand.

We have devoted considerable time to a careful reading of the above book, and have laid it down with mingled feelings of approval and of disappointment. So far as the publishers are concerned, their work has been done in an excellent manner, and the volume is presented in a very attractive form. As will be seen by reference to the advertising columns of Engineering News, two editions are offered to the public at the same time, and the consequence is that the price has been placed at a very low figure. On a comparison of the two it would be found that the copies put forth by Messrs. Wiley & Sons, while not entirely free from typographical errors, have evidently been more carefully revised than those issued by the other house, and some of the errors of the original have been copied in Van Nostrand's edition. Most of all such mistakes are, however, at once discovered on a careful reading of the text. Wiley & Sons have also added, by way of appendix, and as naturally harmonizing with the subject under discussion, several papers by Prof. Thurston, of the Stevens Institute of Technology, which, while they are to be found in various society publications, have never been before collected in book form. As the edition of the Messrs. Wiley & Sons has been specially authorized by Dr. Weyrauch, and he receives a copyright on the same, we should, even if the editions were of equal merit, prefer to contribute towards rewarding the original author for his labor.

The book aims to set forth a new method of calculating the dimensions of the several portions of a structure in iron and steel, for resisting the stresses previously determined by the common statical methods, and naturally considerable space is devoted to the ultimate strength, elastic limits, influence of chemical composition, mechanical treatment, temperature, etc. The attention of the reader is strongly called to the fact that repeated stresses, of less intensity than the breaking stress, may cause a piece to fail, and that the safe stress is one which, for bridges, where unlimited duration is desired, may be repeated an infinite number of times without producing fracture. It is then shown that pieces under a certain permanent stress and an additional, more or less frequent, stress of the same kind from traveling load have a different power of resistance, and that parts which are subject to alternating stresses of tension and compression are most unfavorably situated and have the smallest resisting power. This fact is quite commonly recognized already by good designers in this country, as is shown by the avoidance of such members in the web of a truss, by the introduction of two tension diagonals in such panels of the ordinary quadrangular bridge truss as are subject to a reversal of the shear, and by the addition of tension members in connection with the struts near the middle of the span of a Warren Girder as sometimes built.

As a means of further drawing attention of engineers to these points and of enforcing greater care in proportioning sections for varying forces, this volume will do much good, and we can commend it to the profession for this reason. But we cannot resist the feeling that the experiments are lacking in number, exactness and coincidence of results, and that therefore the formulæ are generalized from insufficient data.

The chapters devoted to the strength of riveted joints and the arrangement of the rivets have served to confirm the opinion that we know very little of the real working strength of many of the complicated connections found necessary in riveted bridges. The transmission of the stresses from the web members to the chord plates in a bridge truss, without straining the angle iron or the vertical plate connection beyond the desired amount, and with an assured economy of material, still seems a difficult problem. Most American engineers would have preferred a chapter on the proportion of eye-bars and pin connections.

One important point in which the formulæ set forth by the writer fail is in not taking account of the length of a compression member. Thus, where a piece is subjected to alternate compression and tension the formula is, the allowable safe stress per square inch for wrought-iron in pounds

$$b = 10{,}000\,(1 - \tfrac{1}{2}\,\frac{max.\ B'}{max.\ B})$$

where B and B′ represent respectfully the greater and the less of the two opposite maxima stresses. Then in applying it to a truss where a diagonal has at one time 9550 units of tension and, at another, 4600 units of compression, he makes

$$b = 10{,}000\,(1 - \tfrac{1}{2}\,\frac{4600}{9550}) = 7586 \text{ lbs.}$$

As 9450 kilograms = 21054 lbs., the cross-section will therefore be 2.8 sq. inches. As no dimensions are given for the truss referred to, there is no means of judging whether the diagonal is five feet long or twenty feet, and he nowhere intimates that the length is a disturbing factor in the calculation for the resistance to compression. We were also surprised that in such a work no allusion was made to the theory that shearing stress is not uniformly distributed over the cross-section of bolts and pins and that hence an increase of section is called for.

The author concludes in the following words:

"If, now, anyone declines to make use of the advantages which the new method presents as regards the saving of material, that is his affair. The construction will not be any the safer thereby; but he who expends the material is only answerable to him who pays for it. It cannot, however, without danger, be allowed to subject pieces which are alternately extended and compressed, and of which an unlimited life is expected, to a stress of 10,000 lbs. per sq. inch. He who will go no further may, at least, calculate the cross-sections for pieces in alternate tension and compression, as in the practice in America, from the formula

$$\text{Cross-section} = \frac{max.\ B + max.\ B'}{10{,}000}.$$

The stresses thus obtained compare not unfavorably with those obtained from the formula based upon Mr. Wohler's law."

We should be glad to hear from some of our readers how much and where the formula credited above to America is used in this country.

NOTES.

The Youngstown, O., rolling mills burned a few days since. Loss $100,000.

An amount of stock sufficient to start the cheap cab enterprise in New York City, has been subscribed, and their appearance is promised in October.

The Akron Iron Company at a special meeting, recently, resolved to increase the capital stock by $75,000, on account of the changes and improvements now being made, and the stockholders will furnish the entire amount in cash. An excursion to the new coal and iron lands of the company in the Hocking Valley is talked of.

The Governor of New York, at Albany has signed the following bills:—

Providing for the Stevenson traction system of towage on the Erie Canal. Providing for a deficiency in the appropriation for ordering repairs of the canals for the fiscal year ending September 30, 1877. Authorizing the Canal Board to close the feeders of the Erie Canal in Rochester. Providing for the introduction of an improved system of steam towage upon the Canals of the State.

A plant has been newly found out in Lukhipur, Hindostan, the leaves of which turn very much to the shape of a grasshopper in proportion as they grow old, till all the parts of the insect so formed become beautifully

developed; and each leaf forming, a separate insect issues out in very beautiful appearance. This plant is known to grow by itself, and no second plant has yet been seen to grow from it.

Millerstown, Pa., was threatened with utter destruction as the result of a singular accident which took place on the evening of June 2nd. According to our despatches, an oil tank was struck by lightning, and in an instant huge flames burst forth and the country was illuminated for miles around. Several other tanks almost immediately took fire, and the scene is described as terrific. A severe storm added to the horrors of the situation. Thousands of barrels of oil and other property were destroyed.

The Urbana, O., Council has decided that the only effectual means by which to obtain an ample supply of water is to construct wells of sufficient capacity, outside the drainage of the city, and erect a pumping machine. H. B. Clinch & Co. submitted a proposition to erect the necessary pumping apparatus of the capacity to furnish one million gallons of water daily, the city to pay the contractor an annual rent of $100 per hydrant, to the number of sixty. If the proposition is accepted the contractor is to begin work within ten days, and have the works in operation on or before November 1.

BAILROAD NOTES.

ERRATA.—In the note in our last issue, referring to the addition being built by the side of the P. C. & St. L. R. R., in Chicago, from Ogden avenue to the Stock Yards Junction, we were in error in stating that the C. B. & Q. R. R. Co. had completed the arrangements for that work; the Union Stock Yards and Transit Co. alone are concerned in the undertaking.

All railway travelers will be pleased to learn that a smoke, spark and cinder-consuming and self-feeding locomotive has been tested on the New York & New England R. R.

The Bedford R. R., 3-feet gauge, from Bedford to Billerica, Mass., eight miles, is being rapidly pushed to completion. Work was begun last fall, and suspended during the winter.

The track on the Rochester & State Line is now laid to Warsaw, N. Y., six miles beyond the last point noted and forty-one miles from Rochester, N. Y. A large quantity of ties are being distributed along the road south of Warsaw.

The Spartanburg & Asheville track is now laid to the South Pacolet River, 19 miles from Spartanburg, S. C., leaving 25 miles yet to reach Hendersonville. Work is progressing steadily and the company hopes to reach Cold Spring Gap in Polk County, N. C., by July 4.

The Albert, New Brunswick road is now completed from Salisbury, N. B., southeast to Hillsboro, 24 miles, and to some coalmines a short distance beyond that town. An excursion train passed over the road recently, and regular trains will run to Hillsboro very soon.

The grading of the Utah Western road is now completed to the tunnel near Stockton, Utah, thirteen miles westward from the terminus at Lake Point, and thirty-three miles from Salt Lake City. The ties are being distributed along the line and the rails have been purchased.

The contract for building the Stratford & Lake Huron road from Stratford, Ont., to Listowell has been let to W. G. Hay, of Listowell, the work to be completed by November. The town of Palmerston has voted a bonus of $21,000 to secure the construction of the road at that point.

Work is in progress on a section of the Putnam & Dutchess road from Newburg, Dutchess & Connecticut road at Clove Branch Junction, N. Y., north to the Clove Spring Iron Works, about three miles. The road was formerly included in the New York, Boston & Montreal combination.

The Narrow Gauge track is laid into Waverly, Ohio, and the work of ballasting the road is progressing. The Company last week received twelve flat and six box cars, and in a few days will have passenger coaches. We understand regular trains will be put on the road about the 15th of June.

It is proposed to build a railroad from San Antonio, Tex., to the Rio Grande at the most convenient point, for the purpose of opening the country west of San Antonio. In view of the importance of such a line in a military point of view, especially in the present disturbed state of the Mexican border, an effort is to be made to secure aid from the Federal Goverment.

The Midland R. R., 3-feet gauge, from Boston to North Reading, Mass, 18 miles, is located and construction commenced. Walter E. Bates, Chief Engineer. It runs nearly parallel with the Boston & Maine R. R. for a large part of the way but crosses it over head in Stoneham. Its location was a matter of much difficulty, and some heavy work in rock cutting will be be required with heavy grades and sharp curves.

A company by the name of New York, Brooklyn & Sea Beach has begun work on a line from East York (just outside of Brooklyn) to Rockaway Beach. Contracts have been let, and it is said that the road is to be completed in July. There are already two railroad routes from New York to Rockaway Beach, besides one partly by railroad and partly by steamboat, and a number of steamboats also run there during the summer.

The Boston, Revere Beach & Lynn R. R., 3-feet gauge, continues to be a success. It is heavily patronized in summer by visitors to Chelsea Beach, and cuts deeply into the traffic of the Eastern R. R. with which it runs parallel. It is proposed to extend it from Lynn to Newburyport, but great difficulty is experienced in finding a location through the city of Lynn. A branch is proposed to Nahant. Notwithstanding its unfinished condition and wretched location and alignment, no accident has yet happened, which may be properly attributed to its good track. Engine and car houses have been built at Winthrop Junction and also a machine shop.

The financial arrangements in the interest of the Montreal, Portland & Boston R. R. and its connections with the Southern Road, which E. H. Goff has been negotiating, have terminated successfully. Hon. Lucius Robinson, of New York, purchased from Mr. Angus his interest in the railway, thereby becoming part owner with Mr. Goff. Mr. Robinson has been appointed general manager, in place of N. A. Smith, resigned. The contractors expect to have the road completed to West Farnham by August 1. It there intersects with the Southeastern & Passumpsic Road, thus completing the Montreal & Boston air line. The company will eventually complete the road through to the Providence line to connect with Portland and Ogdensburg.

Russian railroads date back to 1838. The first line opened was from Zarskoe-Selo and Pawlosk. The road from Warsaw to the Austrian frontier was built immediately afterward, and then the line from St. Petersburg to Moscow. In the beginning of the present reign enormous subsidies were offered by the Government, which resulted in fifty lines being organized. Twenty of these were guaranteed to the full amount of their capital, twenty were partially guaranteed, and ten were built without Government aid. The total length of the roads is 20,000 miles, and the capital of the companies $1,500,000,000. The Government owns fully 50 per cent. of the entire railroad property.

A progress report of the Canada Pacific R. R. has just been laid before the Dominion Parliament. This line, let it be taken where it may, will have a bearing on our own commerce, and ere it is finished may be of considerable interest to us. Its route is practically determined from the head of Lake Superior to the first westward slope of the Rocky Mountains. From Thunder Bay in Lake Superior it runs through the heavy-timbered country on the north side until it strikes the head of the Lake of the Woods at Rat Portage—a lake, the south portion of which is in Minnesota—and 114 miles farther west strikes the Red River of the North, about a hundred miles on an air line from the international line which separates Minnesota and Dakota from the Canadian province of Manitoba. Thence it strikes northwest through the Saskatchewan country in the Canadian Northwest territories, and crosses the Rocky Mountains by the "Tete Jaune" or "Yellow Head" Pass, 1,053 miles from the Red River. Twenty-four miles over the rocks on the confines of Lake Superior have been built, and 226 miles altogether are now under construction. A telegraph wire has been laid as far as Edmonton, on the Saskatchewan, a Hudson Bay Company station, 807 miles west of the Red River, and several hundred miles north of Benton in Montana. This line, now in connection with our Western Union, will shortly be extended eastward to Thunder Bay and westward to the Rocky Mountain Pass, a distance of 1,475 miles. That portion, however, about which uncertainty remains is the one perhaps the most interesting to us. There are enormous difficulties to be overcome in carrying this Canada Pacific railway through the Cascade range, and the question of its Pacific seaport is still a matter of deep consideration with the Canadian engineers and the Canadian Government, and a subject of bitter contention amongst the people of Canada's Pacific province, British Columbia. There is a magnificent harbor at Esquimalt, but this is on Vancouver Island, and the difficulty of crossing from the mainland is great and expensive to overcome. The choice, then, falls between a terminus amongst the fogs and ice in the neighborhood of Alaska—a terminus which would seriously damage the commercial value of the railway—and a harbor in close proximity to the international boundary line. Strategical reasons forbid, of course, the placing a line of railway on the frontier, but the probability of the Canada Pacific ever being required, or of rendering effectual service if required, as a military road, is not, we should imagine, sufficiently strong to outweigh the more immediate considerations of cost, natural advantages and the requirements of commerce. At one time it was almost definitely determined that the road should eventually cross to Vancouver Island and to the port of Esquimalt, but there is now a strong tendency to further examine the line down the valley of the Fraser River to the ocean at Bunard's Inlet.—*N. Y. World*

FLORIDA NOTES.

The Railroad from Jesup, Georgia, through Jacksonville to St. Augustine, is partly completed, but work was stopped owing to failure of contractor. This is but the beginning of a road that will traverse the whole eastern coast of Florida to Key West, and there connect with a short line of steamers to Havana. The Great Southern R. R. Co. hold the charter and propose to re-commence work shortly. This road will open the garden of the State and the great orange-growing region of Indian River to settlers, and it is believed that it will become a popular route to Cuba for invalids and others, avoiding the boisterous passage by Cape Hatteras. It will also be the best line for the transportation of pine-apples, bananas, and other tropical fruits to the northern markets, which now are obliged to depend on vessels, and it is proposed to construct tank cars for the conveying of molasses in bulk The passage from Key West to Havana will occupy but about twelve hours, and freight to New York from Havana will go through in six days. The alignment will be almost perfectly straight and no cuttings of over six feet will be encountered, and no rock work on the entire line. The best of timber for bridges and ties exists in great plenty along the whole line, and no bridges over 150 feet in length will be necessary, except at the crossing of the St. John's river at Jacksonville. It is perfectly safe to say that no railroad in the United States of its length can be constructed cheaper and none that will pay a better dividend to its stock holders.

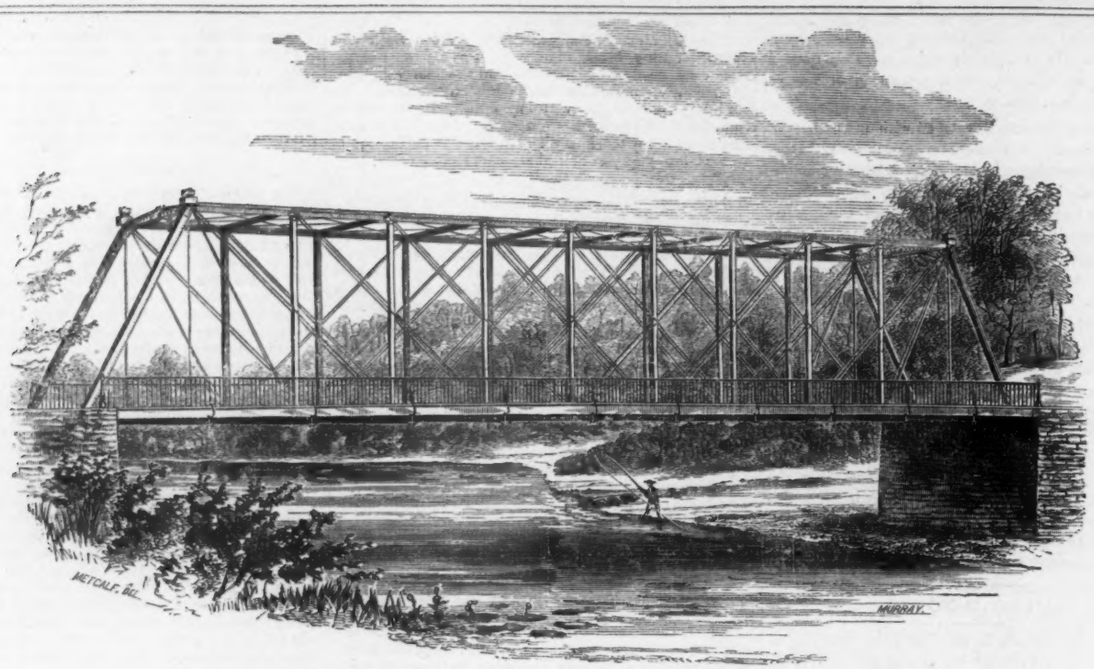
A canal is also proposed from the vicinity of St. Augustine, on the Mantonzas river, to connect with the Halifax river, with a branch to the St. John's river at Lake George. This canal, including the branch, will be 44 miles long, without locks, and will open a direct inland water communication of about 450 miles. The old canal, 26 miles in length, that was commenced before the war, from the St. John's river to the Indian river, north of Sand Point, has been abandoned and in its stead a canal only seven miles long is proposed from Lake Washington to Indian river at Eau Gallæ. This short canal will open a water communication of nearly 1,000 miles, and will enable steamers from Jacksonville to pass into Indian river, bringing the whole of that great orange and other tropical fruit country within seven days of New York. The Indian river country is the garden of the State, where all kinds of tropical fruits can be and are produced in abundance, but it is shut out from the world at present by want of steam communication. The imperative need of the Indian river country is free communication, and they mean to have it without delay. The State Agricultural College is also built at Eau Gallæ, at a cost of $100,000, and it is estimated that in four years over 500,000 oranges will require shipment from this river, not to mention bananas and other tropical fruits.

Another scheme for the relief of this section, is to enlarge the existing canal, 2,000 feet long, at the Haul-over, between Indian river and the Hillsborough river, and dredge about one-half mile in the Hillsborough river. This will give direct communication with the Atlantic at New Smyrna, and open nearly 230 miles of inland water communication. Steamers are now running on both the Hillsborough and Indian rivers, making a portage or transhipment at the Haul-over, and a company has been recently formed to run a line of steamers from Jacksonville to New Smyrna. It is further proposed to connect the waters of Indian river and Biscayne Bay by a canal to pass through Lake Worth, which canal would be 35 miles long, without locks, and would give direct communication with Key West, and form an uninterrupted inland water communication from Indian river to Cedar Keys on the Gulf coast, clear around the peninsula of Florida, a distance of over 600 miles.

Thus it appears that a series of canals aggregating only about 60 miles, easily constructed, and without locks, will give uninterrupted inland water communication from St. Augustine, on the east coast to Cedar Keys on the west coast, entirely around the State, a distance of over 700 miles. The Florida Inland Navigation Co. have been investigating the matter and have already made preliminary surveys. J. FRANCIS LEBARON.

The bids for the improvement of the harbor of Ontonagon, Mich., were opened by Major Henry M. Robert, Corps of Engineers, on Saturday, May 26, with the following results:—Thurlby & Watson, $9,726.00; Simon Emery, $9,280.00; Rosser & Winston, $9,130.50; Harvey & Hubbard, $8,954.25; Edmond Ingalls, $8,880,50; Thos. Keeler, $8,408.00; John E. Thomes, $8,394.90; McDougall & McLennan, $8,176.00; Chas. Fisher, $8,096.00; E. Powell & Sons, $7,933.06; H. J. Lutes, of Ontonagon, $7,655.50.

BOLLER'S work on Highway Bridges again furnishes us with an illustration of an Iron Bridge, which we have pleasure in presenting to our readers on another page.



IRON HIGHWAY BRIDGE. BY CINCINNATI IRON BRIDGE COMPANY.

THE SCIENCE OF ROAD MAKING.

BY CLEMENS HERSCHEL, OF BOSTON,

Civil Engineer, Member of the American Society of Civil Engineers.

(*Continued from page 148.*)

The following table gives the effects of various grades on the amount a horse can pull, and is based on calling the load a horse will pull on a level, one:—

Then, on a grade of	1: 100,	a horse can pull		0.90
" "	1: 50,	" "		0.81
" "	1: 44,	" "		0.75
" "	1: 40,	" "		0.72
" "	1: 30,	" "		0.64
" "	1: 26,	" "		0.54
" "	1: 24,	" "		0.50
" "	1: 20,	" "		0.40
" "	1: 10,	" "		0.25

To determine whether it is most advisable to go over or around a hill, all other considerations being equal, we have this rule: Call the difference between the distance around on a level and that over the hill , *d*, the distance around being taken as the greatest, and call *h*, the height of the hill.

Then in case of a first class road, we go round when *d* is less than 16 *h*.

And in case of a second class road, we go around when *d* is less than 10 *h*.

When the height of a necessary embankment gets to be more than 60 or 65 feet, a bridge or viaduct will be found cheaper, and the same measure, 60 feet, applies in case of tunnels, they being cheaper at that depth than open cuttings.

Under the head of laying out roads, something should be said of their width. Speaking only of such roads as are not apt to turn into streets from their proximity to towns and cities, it is well not to make them too broad, for the less the width, the less the cost of construction and maintenance, and a good 23 feet road is much better than a poor one 40 or more feet wide. Each rod (16½ feet) in width adds two acres per mile to the road. An agreeable form of road is to have on each, or on one side of the same a strip, 5 or 6 feet wide, sodded, and then a sidewalk equal in width to one-eighth the width of the roadway. The intervening strip above mentioned, is planted with trees and at intervals of 200–250 feet furnishes storage places, 30 or 40 long, for the materials used in the road repairs. The width of first, second and third class roadways may be given as 26, 18½ and 13 feet, with a tendency during the last ten years to have none, except in the vicinity of cities, wider than 24 feet, and the rest correspondingly narrower. In view of the changes constantly going on in this country in the value and settlement of land, it would probably be well always to *lay out* a road 50 or 60 feet wide, but to *build* the road proper of the width above indicated.

With all these rules and data in mind, the real work of actually laying out the road on the ground and on a map is next in order, and this comes so entirely within the province of the civil engineer, and is a matter requiring so much explanation and study, that it cannot well be introduced within the limits of this treatise. It is in this part of the work that a little skill and labor well spent may be productive of very great saving in the cost of the whole work and it should not be left to the inexperienced or unskilful.*

MAKING THE ROAD-BED.

Under this head are included, earthworks, drains, culverts, bridges, stay walls, etc., etc., all matters requiring a special kind of skill to construct properly. The writer believes it impracticable to write a book which shall at once be interesting to and therefore valued by the public, and of value to the professional man, and thinks an attempt so to do results always in a failure in both directions. True to the determination expressed in the introduction, he proposes, therefore, to treat under this head mainly with those parts of the subject in which the public at large is most interested, for example, the data for the cost of earthworks, general information relating to drainage, bridges, etc.

EARTHWORKS.

The basis of all values is the daily wages of a common unskilled laborer, and in the data given below, this figure, whatever it is from time to time and in various places, must be taken as unity, or the standard measure.

The cost of earthworks may be divided into three parts—(1) cost of loosening the earth, (2) cost of transport, and (3) cost of forming the transported earth into the desired shape. The cost of the first part depends materially on the kind of earth to be handled. The cost of the second, mainly on the distance the earth is to be moved.

*Gillispie, in his treatise on "Roads and Railroads," gives two forcible instances of the amount those roads which might properly be called *chance* roads, can be improved by a road-maker of skill and understanding. An old road in Anglesea, England, rose and fell, between its two extremeties, twenty-four miles apart, a total perpendicular amount of 3,540 feet; while a new road, laid out by Telford between the same points, rose and fell only 2,257 feet; so that 1,283 feet of perpendicular height is now done away with, which every horse passing over the road had previously been obliged to ascend and descend with its load. The new road is besides two miles shorter. The other case is that of a plank-road built in the State of New York between the villages of Cazenovia and Chittenango. Both these villages are situated on Chittenango Creek, the former being eight hundred feet higher than the latter. The most level common road between these villages, rose, however, more than 1,200 feet in going from Chittenango, to Cazenovia, and rises more than four hundred feet in going from Cazenovia to Chittenango in spite of this latter place being eight hundred feet lower. That is, it rises four hundred feet where there should be a continual descent. The line of the plank-road laid out by George Geddes, civil engineer, ascends only the necessary eight hundred feet in one direction, and has no ascents in the other, with two or three trifling exceptions of a few feet in all, admitted in order to save expense. The scenes of similar possible improvements are scattered all over this and the rest of the States; and these facts are still more or equally to be borne in mind in laying out new roads where the ounce of prevention may take the place of the pound of cure.

(*To be continued.*)

RAILROAD COMPETITION.

Sharp competition has again broken out between the trunk railroad lines from Chicago and the Mississippi Valley to the East. Not content with reducing the fare to a point where it is more than doubtful whether any profit remains for the corporations, the companies are rivaling one another in fast trains. In some cases one road gains over another the trifling advantage of landing its passengers in New York an hour or two ahead of competitors. It is well known that trains at high speed are much more detrimental to rolling-stock and permanent way than cars run at a moderate rate, and the slight saving in time, especially when coupled with a reduction in the price of tickets is decidedly the reverse of economical. We should also fear that this shortening of the time table would encourage a certain recklessness in running and in making time when a train was a little behindhand, which would be far from reassuring to the passengers; to be landed in New York twenty minutes or an hour in advance of travelers by another line will not compensate the majority of the passengers for any increased risks.

Since writing the above few lines our eye has fallen upon the following article from the *Railway Age* which is timely and suggestive. It is entitled—

COMBINATION INSTEAD OF COMPETITION.

The hope expressed by the chairman of the Great Western Railway Company, of Canada, at the recent meeting of that body, that "a general combination of railways would succeed the present universal competition," expresses also the feeling of an increasing number of thinking men in this as well as in other countries. The experiment of competition has been tried to the fullest extent in the United States, and with what results? The trunk lines that engaged in the fierce war last year carried freight in enormous quantities at an actual loss, and had those rates continued would ere long have been bankrupted. Meantime they were compelled to the closest economy, resulting in the partial cessation of improvements and additions—thus crippling many branches of manufacture—and in cutting down the pay of their employees and turning many adrift, bringing trouble and want into thousands of homes, and loss into wide circles of business. On the other hand, the transportation business was demoralized by the unreasonably low rates adopted, and the fluctuations and uncertainties which they involved, and now, when an attempt is being made by the railways to recover in part their losses, by asking fair compensation, people refer to the rates paid during the "war," and think that they are being imposed upon. Finally, papers like our neighbor the Chicago *Tribune*, which applauded the destructive competition as a great thing for the shippers, unmindful of the ruin which it was bringing upon railway owners, now turn upon the companies when they increase their charges, and denounce the "outrageous fluctuations in rates," which is the legitimate result of unrestrained competition.
